Foreword xix
Preface xxi
Acknowledgements xxiii

Part I
Introduction

1. Pharmacogenomics and Stratified Medicine 3

Sandosh Padmanabhan

1.1 Overview 3
1.2 The Genetic Basis of Drug Response and Adverse Effects 5
1.3 Single-Gene Studies 5
1.4 Genome-Wide Association Studies in Pharmacogenomics 12
1.5 The Road to Personalization and Stratification 13
1.6 Pharmacogenetic Biomarkers and Companion Diagnostics 13
1.7 Economic Challenges 19
1.8 Conclusions 21
References 22

Part II
Basic Genetics

2. Basic Genetics: The Cell, Mitosis and Meiosis, and Mendelian Laws 29

Guan Wang

2.1 Overview of the Cell: Anatomy, Components, and Function 29
2.2 Cell Reproduction: Cell Cycle and Mitosis 30
2.3 Meiosis 33
2.4 Mendelian Laws 35
2.5 Public Databases for Biomedical Research in Humans 38
2.6 Conclusion 39
Glossary 39
Acknowledgments 40
References 40

3. The Human Genome, Gene Regulation, and Genomic Variation 41

Kathleen M. Murphy, Aislinn Cooper, and Edward S. Tobias

3.1 Overview: Structure of the Human Genome 41
3.2 Gene Structures 44
3.3 Gene Expression 45
3.4 Gene Regulation 46
3.5 Genomic Variation 51
3.6 Conclusion 56
References 56

4. Epigenetics 57

Tony McBryan and Peter D. Adams

4.1 Overview 57
4.2 DNA Methylation 57
4.3 Histones and Variants 61
4.4 Epigenetic Disorders and Therapies 65
4.5 Conclusion 66
References 66

Part III
Experimental and Discovery Platforms

5. Animal Models in Pharmacogenomics 73

Erin Olson and Delyth Graham

5.1 Overview 73
5.2 Rodent Models 74
5.3 Nonrodent Models of Human Disease 79
5.4 Genetic/Genomic Resources 79
5.5 Ethical Issues of Animal Experimentation 80
5.6 Caution and Limitations 80
5.7 Applications of *in vivo* Models in Pharmacogenomic Research 81
5.8 Rodent Models in Pharmacogenomics 82
5.9 Conclusion 85
References 85

6. Human Lymphoblastoid Cell Lines in Pharmacogenomics 89

Jae-Pil Jeon

6.1 Overview 89
6.2 Generation of LCLs 90
6.3 Biological Characteristics of LCLs 95
6.4 Potentials and Limitations of LCL Applications 97
6.5 Future Perspectives 105
Acknowledgments 107
References 107

7. Liver Expression Quantitative Trait Loci (eQTL) and Related Approaches in Pharmacogenomic Studies 111

Dylan M. Glubb, Amy S. Etheridge, Eric Seiser, and Federico Innocenti

7.1 Overview 111
7.2 Liver eQTL Studies 112
7.3 Future Directions 117
7.4 Conclusion 120
Acknowledgments 120
Glossary 121
Acronyms and Abbreviations 121
References 121

8. Next-Generation Sequencing 125

Pawel Herzyk

8.1 Overview 125
8.2 First-Generation Sequencing: Chain Termination Method 125
8.3 The Concept of Next-Generation Sequencing 126
8.4 Application-Independent Data Analysis 129
8.5 Genomic Applications 131
8.6 Transcriptomic Applications 133
8.7 Epigenomic Applications 135
8.8 Metagenomic Applications 137
8.9 Conclusions 141
References 141

9. Proteomics 147

Holger Husi and Amaya Albalat

9.1 Overview 147
9.2 Data Acquisition 148
9.3 Data Analysis 163
9.4 Discovery and Validation 167
9.5 Personalized Medicine 172
9.6 Conclusions 172
Acronyms 173
References 173

10. Metabolomics 181

Karl Burgess, Naomi Rankin, and Stefan Weidt

10.1 Overview 181
10.2 Metabolomics Techniques and Technologies 184
10.3 Analytical Platform 187
10.4 Analysis of Metabolomic Data 197
10.5 Conclusion 200
References 201

11. Stem Cells 207

Komal Loya

11.1 Overview 207
11.2 Stem Cell Types 208
11.3 Stem Cell Culture Methods 211
11.4 Molecular Signatures of Stem Cells 212
11.5 Epigenomics of Stem Cells 215
11.6 Pharmacogenomics of Stem Cells 218
11.7 Potential of Stem Cells 219
11.8 Future Prospects 226
Abbreviations 227
References 228

Part IV

Statistics, Bioinformatics and Databases

12. Fundamentals of Complex Trait Genetics and Association Studies 235

Jahad Alghamdi and Sandosh Padmanabhan

12.1 Overview 235
12.2 The Phenotype 235
12.3 Population Genetics 239
12.4 Association Studies 247
12.5 Conclusions 256
References 256

13. Bioinformatics: Concepts, Methods, and Data 259

Scott W. Robinson, Avid M. Afzal, and David P. Leader

13.1 Overview 259
13.2 Analysis of Sequences of Nucleic Acids and Proteins 260
13.3 Molecular Evolution and Phylogenetics 264
13.4 Molecular Graphics and Protein Modeling 269
13.5 Bioinformatics Databases 276
Glossary 284
References 284

14. PharmGKB: The Pharmacogenomics Knowledgebase 289

Julia M. Barbarino, Michelle Whirl-Carrillo, Teri E. Klein, and Russ B. Altman

14.1 Overview 289
14.2 The PharmGKB Website 290
14.3 Variant Annotations 291
14.4 Clinical Annotations 294
14.5 VIPs and Pathways 297
14.6 Clinical Implementation: Consortia, CPIC, and Dosing Guidelines 301
14.7 Projects in Development 303
14.8 Conclusion 304
Glossary 305
Acronyms and Abbreviations 305
Acknowledgments 306
References 306

Part V

Clinical Trials

15. Clinical Trials in Pharmacogenomics and Stratified Medicine 309

Sandosh Padmanabhan

15.1 Overview 309
15.2 Phase I Studies 309
15.3 Phase II Studies 312
15.4 Phase III Studies 314
15.5 Phase IV Trials 319
15.6 Retrospective Analysis of Clinical Datasets 319
References 319

Part VI

Fundamental Pharmacogenomics

16. CYP450 and Ethnicity 323

Joseph McGraw

16.1 Overview 323
16.2 Variation: Importance of Race/Ethnicity 326
16.3 Variation: CYP450 Phenotyping 327
16.4 CYP450 Variation in Different Racial/Ethnic Populations—CYP450 Families 329
16.5 Future Perspectives 337
References 337

17. Pharmacokinetic Pharmacogenomics 341

Safaa Mohammed M. Alsanosi, Craig Skiffington, and Sandosh Padmanabhan

17.1 Overview 341
17.2 Principles of Pharmacokinetics 341
17.3 ADME: Pharmacogenomics 349
17.4 Conclusions 360
References 361

18. Pharmacodynamic Pharmacogenomics 365

Linsay McCallum, Stefanie Lip, and Sandosh Padmanabhan

18.1 Overview 365
18.2 Basic Pharmacodynamics 365
18.3 Pharmacodynamic Pharmacogenetics 373
18.4 Conclusion: Pharmacodynamic Pharmacogenomics into Clinical Practice 379
Glossary 380
Acronyms and Abbreviations 381
References 381

19. MicroRNA: Regulation of P450 and Pharmacogenetics 385

Miki Nakajima and Tsuyoshi Yokoi

19.1 Overview 385
19.2 miRNA Biogenesis 385
19.3 miRNA Function 386
19.4 miRNA Target Identification 386
19.5 Regulation of Drug-Metabolizing P450s 389
19.6 Regulation of Cancer-Related P450s 391
19.7 Modulation of miRNA Expression and its Toxicological Outcome 394
19.8 miRNA Pharmacogenetics Associated with Disease or Drug Response 395
19.9 miRNAs as Biomarkers and Therapeutic Targets 397
19.10 miRNAs and Drug Response 397
19.11 Conclusions 397
Glossary 398
Abbreviations 398
References 398

Part VII
Application in Therapeutics

20. Adverse Drug Reactions 405

Lauren Walker, Vincent Yip, and Munir Pirmohamed

20.1 Overview 405
20.2 Phase I Metabolism 408
20.3 Phase II Metabolism 410
20.4 Type B Adverse Drug Reactions 414
20.5 Conclusion 424
Abbreviations and Acronyms 425
References 426

21. HLA and the Pharmacogenomics of Drug Hypersensitivity 437

Katie D. White, Silvana Gaudieri, and Elizabeth J. Phillips

21.1 Overview 437
21.2 Introduction 437
21.3 Classification of Drug Hypersensitivity Syndromes 440
21.4 Immunopathogenesis of Drug Hypersensitivity Syndromes 442
21.5 HLA and Hypersensitivity Reactions 444
21.6 Stratified Approaches to Prevent Drug Hypersensitivity and their Translation into Clinical Medicine 455
21.7 The Future Direction of Stratified Medicine in Drug-Induced Hypersensitivity 458
Acronyms 459
References 459

22. Drug-Induced Liver Injury 467

Thomas J. Urban and Hans Tillmann

22.1 Overview 467
22.2 Epidemiology and Public Health Impact 467
22.3 Etiology 468
22.4 Pharmacogenomics and Stratified Medicine in DILI 469
22.5 Difficulties in Identifying Biomarkers for DILI 470
22.6 DILI-Associated Genetic Variants 471
22.7 Utility of Dili Risk Variants in the Clinic 472
22.8 Future Directions 473
22.9 Conclusions 475
References 475

23. Hemostasis and Anticoagulants 479

Matthew R. Wilson and R. Campbell Tait

23.1 Overview 479
23.2 Hemostasis 479
23.3 Indications for Anticoagulation 482
23.4 Parenteral Anticoagulants 484
23.5 Oral Anticoagulants 488
23.6 Conclusion and Directions for Future Research 494
References 494

24. Pharmacogenomics of Warfarin 497

Ann K. Daly

24.1 Overview 497
24.2 Pharmacology of Warfarin 498
24.3 Nongenetic Factors Affecting Warfarin Dose Requirement 499
24.4 Genes with Major Effects on Warfarin Dose Requirement 500
24.5 Additional Pharmacogenomic Factors Affecting Warfarin Dosage 502
24.6 Application of Pharmacogenomics to Warfarin Prescription 503
24.7 Conclusion and Future Research Directions 504
References 504

25. Pharmacogenomics of Clopidogrel 509

Betti Giusti, Claudia Saracini, Silvia Galora, and Rossella Marcucci

25.1 Overview 509
25.2 Clopidogrel Response Variation 514
25.3 Genetic Dissection of Clopidogrel Response 518
25.4 Current Status 527
25.5 Conclusions and Future Directions 535
Abbreviations 536
References 536

26. Pharmacogenetics of Antidepressant Drugs 543

Chiara Fabbri, Alessandro Minarini, Yoshihiko Matsumoto, and Alessandro Serretti

26.1 Overview 543
26.2 Candidate Gene Studies 544
26.3 Genome-Wide Approaches 553
26.4 Conclusion 555
Key Concepts 556
Glossary 556
Acronyms and Abbreviations 556
References 557

27. Personalized Medicine of Alzheimer's Disease 563

Ramón Cacabelos, Pablo Cacabelos, and Clara Torrellas

27.1 Overview 563
27.2 Toward a Personalized Medicine for Dementia and Neurodegenerative Disorders 564
27.3 Genomics of Alzheimer's Disease 565
27.4 Pathogenic Events 565
27.5 Biomarkers and Comorbidity 569
27.6 Therapeutic Strategies 571
27.7 Pharmacogenomics 573
27.8 Future Perspective 584
27.9 Conclusion 585
Appendix A 586
Appendix B 608
References 611

28. Asthma 617

Dominick Shaw, Michael Portelli, and Ian Sayers

28.1 Overview 617
28.2 Clinical Aspects 618
28.3 Asthma Pathophysiology 623
28.4 Current Management of Asthma 629
28.5 Stratified Medicine for Asthma 631
28.6 Drug Development in Asthma and Emerging Targets 645
28.7 Conclusions and Future Directions 647
Acknowledgments 647
References 647

29. Rheumatoid Arthritis 653

Jisna R Paul, Deepali Sen, and Prabha Ranganathan

29.1 Overview 653
29.2 Pharmacogenetics of Nonbiologic DMARDs 655
29.3 Pharmacogenetics of Biologic DMARDS 668
29.4 Conclusions and Future Directions 674
References 674

30. Pharmacogenomics of Oral Antidiabetic Drugs 683

Vangelis G. Manolopoulos and Georgia Ragia

30.1 Overview 683
30.2 Genetic Basis of Diabetes 683
30.3 Management of Diabetes 684
30.4 The Need for Pharmacogenomics and Stratified Medicine 685
30.5 Genetic Variants Associated with Response to Oral Hypoglycemic Agents 685
30.6 Stratified Oral Antidiabetic Medicine: Pharmacogenomics Application 709
30.7 Conclusions: Future Perspectives 710
Abbreviations 710
References 710

31. Genomics and Pharmacogenomics of Lipid-Lowering Therapies 715

Kieran F. Docherty and Sandosh Padmanabhan

31.1 Overview 715
31.2 Lipid Metabolism 716
31.3 Lipids and CVD Risk, Epidemiology, and Public Health Impact 718
31.4 Genetic Basis of Lipid Disorders and Lipid Levels 722
31.5 Conclusion and Future Directions 741
References 742

32. Hypertension Pharmacogenomics 747

Yan Gong, Caitrin W. McDonough, Sandosh Padmanabhan, and Julie A Johnson

32.1 Overview 747
32.2 Epidemiology and Public Health Impact 747
32.3 Genetic Basis of Hypertension 749
32.4 Need for Stratified Approaches to Treatment with Antihypertensives 754
32.5 Pharmacogenomics of Blood Pressure Response to Antihypertensive Drugs 758
32.6 Pharmacogenomics of Antihypertensive Treatment—Related Outcomes 764
32.7 Future Perspectives 771
References 772

33. QTc and Sudden Cardiac Death 779

Catriona Brown and Sandosh Padmanabhan

33.1 Overview 779
33.2 Genetic Syndromes 784
33.3 Drug-Induced Variation in QTc 787
33.4 Public Health Impact 796
33.5 QTc in New Drug Discovery and Drug Safety 797
33.6 Pharmacogenomic Studies 798
33.7 Future Directions 801
Glossary 802
Acronyms and Abbreviations 803
References 803
Suggested Websites 806

34. Stratified Medicine for Pancreatic Cancer 807

David K. Chang, Nigel B. Jamieson, Sean M. Grimmond, and Andrew V. Biankin

34.1 Overview 807
34.2 Current Treatment Paradigm 807
34.3 Stratified Therapeutic Approach 808
34.4 Preclinical Models of Pancreatic Cancer 812
34.5 Central Knowledge Database 812
34.6 Biorepository and Privacy Issues 813
34.7 Conclusion 813
References 813

35. Pharmacogenomics in Anesthesia 815

Shiv Kumar Singh and Tushar Dixit

35.1 Overview 815
35.2 Pharmacokinetic Pharmacogenetics In Anesthesia 815
35.3 Pharmacodynamics 820
35.4 Conclusion 830
References 830

36. Tuberculosis 835

Geetha Ramachandran and Soumya Swaminathan

36.1 Overview 835
36.2 TB Etiology and Natural History 835
36.3 Burden of TB 836
36.4 Burden of TB Among Children 838
36.5 TB Diagnosis 838
36.6 Chemotherapy for TB 840
36.7 Risk Factors: Genetics, HIV, Diabetes, and Smoking 842
36.8 TB in Children 844
36.9 Pharmacogenomics of TB 845
36.10 Pharmacogenomics and TB 845
36.11 Conclusion 853
References 853

37. Hepatitis C Virus 859

A.J. Thompson, P. Clark, and A. Aghemo

37.1 Overview 859
37.2 *IL28B* Polymorphism and HCV Outcomes 860
37.3 *ITPA* Polymorphisms and Ribavirin-Induced Hemolytic Anemia 864
37.4 Genetic Determinants of Liver Fibrosis Progression 865
37.5 Clinical Translation 866
37.6 Conclusion 872
Acknowledgments 872
Disclosures 872
Abbreviations 872
References 873

38. Pharmacogenomics of Antifungal Agents 879

H.R. Ashbee and M.H. Gilleece

38.1 Overview of Antifungal Therapy 879
38.2 Public Health Impact of Fungal Diseases 886
38.3 The Need for Pharmacogenomics and Stratified Medicine 886
38.4 Genetic Variability Associated with Antifungal Drugs 887
38.5 Current Successes in Stratified Medicine 895
38.6 Future Perspectives 896
References 896

39. Advances in Understanding and Treatment of Human African Trypanosomiasis: Divergent Diseases Caused by Distinct Parasites 901

Federica Giordani, Roy Mwenechanya, and Michael P. Barrett

39.1 Overview 901
39.2 The Genetics of Trypanosome Lytic Factors and Parasite Factors Enabling Protection Against Lysis 903
39.3 Immune Responses and Immunoavoidance 905
39.4 Pathologies Associated with Hat 906
39.5 Diagnosis of Hat 907
39.6 Staging the Disease 908
39.7 Treatment 909
39.8 Conclusions and Future Perspectives 913
Glossary 914
References 914

Part VIII

Implementation and Regulatory

40. Implementing Clinical Pharmacogenetics: Point-of-Care and Pre-Emptive Testing 921

Stuart A. Scott

40.1 Overview 921
40.2 Clinical Pharmacogenetics and Implementation 922
40.3 Point-of-Care Pharmacogenetic Testing 924
40.4 Pre-Emptive Pharmacogenetic Testing 925
40.5 Conclusion and Future Perspectives 927
References 928

41. Ethical Considerations in Pharmacogenomic Testing and Research in Pediatrics **931**

Chi Dang Hornik, Cait O'Donnell, and Raymond Barfield

41.1 Overview 931
41.2 Historical Perspective 933
41.3 Ethical Significance of Benefit, Risk, and Uncertainty in Pediatric Pharmacogenomics 935
41.4 Federal Regulations and National Healthcare Priorities Related to Pharmacogenomics 943
41.5 Translation of Pharmacogenomics into the Clinical Setting 945
41.6 Future Implications of Pharmacogenomics Testing in Children 946
41.7 Conclusion 948
References 948

42. PGx/Biomarker Utilization for Regulatory Decision Making **951**

Yu Sakamoto, Yasuto Otsubo, Akihiro Ishiguro, and Yoshiaki Uyama

42.1 Introduction 951
42.2 Regulatory Activities and Guidelines Relating to PGx/Biomarker 951
42.3 Biomarker Qualification 956
42.4 Clinical Trial Design and Drug Development Utilizing PGx/Biomarker 960
42.5 Future Challenges 963
Disclaimer 964
Glossary 964
Acronyms and Abbreviations 964
References 965

Part IX

Global Perspective

43. Population Diversity and Pharmacogenomics in Africa **971**

Collen Masimirembwa, Collet Dandara, and Julia Hasler

43.1 Overview 971
43.2 Population Diversity in Africa 973
43.3 Population Genetics, Diversity, Ancestry, and Admixture 979
43.4 Pharmacogenomics in Africa 985
43.5 Future Perspectives 992
43.6 Conclusions 994
Key Concepts 994
Acknowledgments 995
Glossary 995
Acronyms and Abbreviations 995
References 996

44. Pharmacogenomics in China **999**

Wei Zhang, Hong-Hao Zhou, Zhao-Qian Liu, Xiao-Ping Chen, and Yi-Jing He

44.1 Overview 999
44.2 Pharmacogenomics of Drug-Metabolizing Enzymes in Chinese Populations 999
44.3 Pharmacogenomics of Drug Transporters in Chinese Populations 1002
44.4 Pharmacogenomics of Drug Receptors in Chinese Populations 1006
44.5 Pharmacogenomics of ION Channels in Chinese Populations 1009
44.6 Environmental Factors in Drug-Metabolizing Enzyme and Transporter Activity 1011
44.7 Translational Approaches to Pharmacogenomics in China 1012
44.8 Conclusion and Future Perspectives 1012
Acknowledgments 1012
References 1012

45. Pharmacogenomics in Brazil **1015**

Guilherme Suarez-Kurtz and Mara Helena Hutz

45.1 Overview 1015
45.2 The Brazilian Pharmacogenetics Network–Refargen 1015
45.3 PGX of Immunosuppressants in Renal Transplant Patients 1028
45.4 PGX of Antipsychotics in Schizophrenic Patients 1030
45.5 Conclusions 1032
Acknowledgments 1033
References 1033

46. Pharmacogenomics in India **1037**

Umamaheswaran Gurusamy and Deepak Gopal Shewade

46.1 Overview 1037
46.2 Indian Population Structure and Diversity 1038
46.3 Frequency Distribution and Pattern of Genetic Variants of Pharmacogenes 1039
46.4 Pharmacogenetic Studies in India 1052
46.5 Conclusions and Future Directions 1056
References 1057

Foreword

The *Handbook of Pharmacogenomics and Stratified Medicine*, edited by Sandosh Padmanabhan, has been designed to bring clinicians and biomedical scientists up to date with the quickly expanding field of pharmacogenomics, which is rapidly moving into everyday clinical practice. All 46 well-crafted chapters, including several consisting of practical clinical examples, provide an excellent grounding in pharmacogenomics in all its aspects.

Clear and well-designed figures and tables take us on an exciting journey from the empirical medicine of the past through the development of drug response biomarkers and so-called companion diagnostics to the stratified medicine that we either increasingly practice or will be practicing in the near future.

The timing of the publication of this handbook is excellent, as it follows and expands on the recent report on stratified medicine published by the Academy of Medical Sciences as well as the increasing consensus among major pharmaceutical companies that the momentum is there for stratified medicine not only in cancer but in several other common diseases of our civilization. Publication also coincides with several public-private innovation initiatives in stratified medicine, including the Stratified Medicine Scotland—Innovation Centre and the consultation led by the UK Technology Strategy Board on the Catapult Related to Stratified Medicine and Diagnostics.

If you, as a clinician or scientist, hope to become a part of the pharmacogenomic revolution in healthcare, the *Handbook of Pharmacogenomics and Stratified Medicine* is for you.

Anna Dominiczak

Regius professor of medicine,
vice-principal and head of the College of Medical,
Veterinary and Life Sciences,
University of Glasgow, UK
Glasgow, 28 August 2013

Preface

The last decade has seen an exponential growth of genomics in terms of technological innovation and the mapping of DNA sequence variants to a multitude of traits. At the same time, there has been a steady increase in the number of drug labels that have been updated with relevant US FDA pharmacogenetic information and recommendations. Moreover, the pharmaceutical industry is actively leveraging pharmacogenomics to achieve more effective and efficient clinical drug development. The success of companion diagnostics in cancer therapy has provided a strategic direction for rapid progress in the field, with the European Medicines Agency and the US Food and Drug Administration now providing explicit guidance to industry and researchers.

Escalating investment in pharmacogenomics by industry, academia, government, and institutions reflects recognition of the discipline's value. Pharmacogenomics' evolving maturity is highlighted by pragmatic terminology such as *stratified medicine*, which "reflects the realistic effects of medicines at population level." This distancing from the term *personalized medicine* "reflects the possibly over-ambitious promise of individualized unique drug targeting and development." There is now a need for a well-organized technology infrastructure, professional training, and an internationally aligned ethical, legal, and regulatory framework to transform discoveries into clinically useful applications. A rapid transition from hypothesis to clinical application requires a multidimensional effort involving basic genetics, pharmacology, clinical trials, biostatistics, epidemiology, and ethical and regulatory issues.

The goal of *Handbook of Pharmacogenomics and Stratified Medicine* is to be accessible to readers from all of the disciplines just listed by providing a detailed overview of pharmacogenomics and stratified medicine. The first half of the book covers the principles of genetics, analysis, technology, and pharmacology, which together form the foundation for the second half focussing on disease domains. Each disease specific chapter first provide background on disease, epidemiology, and treatment before turning to the relevant pharmacogenomics.

It is envisaged that this book will help interested clinicians and nonclinicians obtain a broad and reasonably in-depth understanding of the field of pharmacogenomics and, in so doing, enhance research and quickly move discoveries into clinical implementation.

Sandosh Padmanabhan

Acknowledgements

The development and completion of this book would not have been possible without the help and support of some very talented and committed individuals. Firstly, I would like to thank Christine Minihane, who first discussed with me the idea of developing a book that would help a wide spectrum of readers who are interested in the growing field of pharmacogenomics. Christine's successor Graham Nisbet continued supporting development of this book and without his encouragement, this book would not have been completed. I am very grateful to the excellent support from Catherine A Van Der Laan at Elsevier during all the stages of the project.

I would also like to express my thanks to all of the book's contributors. Many of them have busy schedules filled with clinical and research commitments. It is greatly appreciated that, because of them, all of the chapters are of high quality and will enhance the value of the Handbook of Pharmacogenomics and Stratified Medicine to its readers. In addition, I am grateful to Professor Anna F Dominiczak for writing the foreword.

A team of undergraduate medical and genetics students at the University of Glasgow volunteered to help with illustrations and proofreading; and I am grateful to them all:

- Illustrators: Stefanie Lip, Duncan Henderson, Abigail Little, Hannah Whittingham, Beatrice Tan, Caitlin McNeill, Ananya Das and Greg Marlow.
- Cover design: Dr. Stefanie Lip.
- Proofreading: Nadeem Ahmed, Sonam Ansel, Hnin Aung, Avirup Chowdhury, Ryan Clark, Holli Coleman, Sinead Corbet, Timothy Cryle, Caitlin Doyle, Nora Gonzalez, Manimaalini Kunasegaran, Jun Lau, Prasanna Partha Sarathy, Euan Paterson, Paul Purvis, Elizabeth Twynam-Perkins, Naoise Smyth, and Arthur Woo.

1.1 OVERVIEW

Drugs are the cornerstone of modern therapeutics. Most of them are currently prescribed empirically based on the physician's assessment of a patient's clinical signs, family history, and probability that a certain drug or therapy will benefit the patient. However, advances in our understanding of the molecular basis of disease are redefining how diseases are classified and present a powerful new dimension for further tailoring treatments to individuals. The principle underpinning drug therapy is that its benefit should outweigh its risks. But in many cases, assessing the balance between risk and benefit may still be a gray area; for example, therapies that provide symptomatic benefits but shorten life may be appropriate in patients with serious and highly symptomatic diseases such as heart failure or cancer.

Large randomized clinical trials (RCTs), meta-analysis, and evidence-based medicine are used to deduce the probability that a drug will work for a specific condition (i.e., provide the benefit of drug therapy). Evidence from RCTs that the drug is appropriately safe and effective is derived statistically from analysis of patient populations participating in these trials; it provides probabilities that are presumed to reflect benefit in the overall population or in specific patient subgroups. Additionally, RCTs define the relationships between dose (or plasma concentration) and benefit–risk ratio, and they establish the population average dose for initiation of therapy. This is the primary requirement for approval of a drug for use. However, it is rare for a drug to be safe or effective for everyone, and individual patients often display striking variability in drug response that requires drug doses that are different from the "average dose." One analysis of drug efficacy from published data showed an 80% response for Cox-2 inhibitors, but the lowest response was 25% for cancer chemotherapy, indicating that in most cancer patients a treatment will only generate severe side effects without treating the disease itself [1,2]. Rates of response to drug treatment are only 30–60% in most common diseases, indicating that the common drug blockbuster strategy ("one drug fits all") may need to be revised according to individual responses [1].

Drug safety varies from drug to drug and from disease to disease, but many drugs have some side effects of clinical

importance. Approximately 7% of hospital admissions and many post-marketing drug withdrawals are due to adverse drug reactions (ADRs) [3]. Some adverse effects are so common and classically associated with certain drugs that they are identified very early during clinical use. On the other hand, serious adverse effects may be sufficiently uncommon that they escape detection for many years after a drug has been licensed. This is despite intensive efforts by pharmaceutical companies to develop safer drugs and efforts by regulatory agencies to maintain strict safety guidelines [4–6]. Throughout the drug development process, there are two simple realities: people exhibit variable responses to medicines, and unexpected findings are routine [7].

In general, for most commonly used drugs there is no major clinical impact, as many drugs (like nonsteroidal anti-inflammatory drugs or proton-pump inhibitors) work for almost all relevant patients. For other drugs, although responses are variable, there is at present no way to identify patients who are likely to respond well; therefore, a trial-and error approach is followed until a satisfactory response is attained.

Interindividual variation of drug response is caused by a combination of genetic and environmental factors as well as by patient characteristics that can affect the drug's pharmacokinetics and/or pharmacodynamics (Figure 1.1). The effects of some of these variables are obvious (e.g., noncompliance) or addressable (e.g., dose adjustments in patients with impaired kidney function), whereas the mechanisms of many other influences on drug response remain unstudied or unexplained. Data from twin and family studies demonstrate higher interindividual variability than intraindividual variability, indicating the role of shared inherited factors in determining drug response variability [8]. One of the methods for estimating the genetic fraction of a phenotypic variation is to calculate the heritability of the trait. For drug response phenotypes, it is estimated that 20–95% variability in drug disposition and effects may be due to genetic factors [9] (see Chapter 12). These support the notion that information on an individual's predisposition to drug efficacy or toxicity will enable targeted therapy and avoid the drawbacks of the current trial-and-error approach.

Furthermore, rapid advances in genomics and molecular biology are revealing the presence of distinct subpopulations within particular clinical presentations that may be amenable to specific therapies. Classification of patients into these subtypes of disease using diagnostic markers adds another dimension to tailored therapy, where accurate definition of the disease subtype can lead to targeted (in contrast to trial-and-error) treatment.

FIGURE 1.1 Factors involved in interindividual variation in drug response.

BOX 1.1 Historical Aspects of Pharmacogenomics

Recognition of interindividual variability in xenobiotic toxicity stretches back to Pythagoras (c. 580–500 BC) who proscribed fava beans, possibly related to hemolytic syndrome associated with the ingestion of undercooked fava beans. It is now recognized that the underlying cause of this syndrome is a mutation in the gene encoding glucose-6-phosphate dehydrogenase (G6PD), resulting in deficiency of the enzyme. Genetic variation in this gene still has major implications in clinical practice. For example, the recently licensed uricosuric drug rasburicase contains an FDA label warning about G6PD deficiency. In the early 50's phenotype-driven assessment of variation in drug-metabolizing enzyme genes was used to define an individual's N-acetylation capacity as slow or fast (phase II enzyme), whereas debrisoquine hydroxylation was used to define the activity of the phase I cytochrome P450 enzyme (CYP2D6) [10–12].

Subsequent advances in molecular genetics led to the molecular characterization of the defects underlying the debrisoquine hydroxylase or CYP2D6 polymorphism, which included not only polymorphisms but also gene duplication, with individuals having 8–13 copies of the gene [13]. The term "pharmacogenetics" was coined by Friederich Vogel in 1959 [14] to define a new science applying genetics and pharmacology to the study of the influence of inheritance on drug response, but it was only after the human genome project that research in this area accelerated and the timeline is summarized in Figure 1.2.

1.2 THE GENETIC BASIS OF DRUG RESPONSE AND ADVERSE EFFECTS

The term *pharmacogenetics* generally implies the clinical effects of a single or a few gene variants and the associated investigations limited to these loci. It is evident that most genetic variability in drug response is multifactorial, influenced by numerous genes with compensatory or overlapping roles. Consequently, pharmacogenetics has evolved into *pharmacogenomics*, which uses a whole-genome approach, including assessment of gene expression and all pathways to dissect the basis of variability in drug response [14]. The transition from pharmacogenetics to pharmacogenomics was greatly facilitated by the completion of the human genome sequence, the international HapMap project, and advances in high-throughput genotyping, gene expression profiling, next-generation sequencing, and so forth. Pharmacogenomics can be also defined as the combination of pharmacology and genomics at both population and patient levels to advance drug research and development and to manage drug selection and dosing [15].

The first evidence that polymorphisms in drug-metabolizing enzymes have clinical effects was the observation of slow acetylation in relation to isoniazid. Genetic variation in genes involved in drug metabolism may decrease functional activity or expression of the metabolizing enzymes and can give rise to distinct individual phenotypes ranging from poor metabolizer (PM), intermediate metabolizer (IM), extensive metabolizer (EM), and ultrarapid (UM) metabolizer states that have an impact on drug pharmacokinetics and hence drug response (see Chapter 17). Pharmacodynamic pharmacogenomics is the study of altered response to drugs associated with genetic polymorphisms of genes encoding for drug targets and associated modifiers or key proteins (see Chapter 18).

Progress in identifying genetic variation that affects drug response is accelerating, with the FDA including pharmacogenomic information on 38 different genes on relevant drug labels so far (Table 1.1) [16]. However, there are major challenges in translating many of the other associations into clinical use. The influence of some these genetic variations on therapy is summarized below (and in more detail in later chapters).

1.3 SINGLE-GENE STUDIES

1.3.1 Predicting Efficacy

The single-gene approach to targeted therapy can be traced back to as early as 1896, when Sir George Beatson reported clinical improvement in three young women with locally advanced breast cancer following surgical oophorectomy [1]. Landmark studies by Jensen, Lippman, and McGuire, among others, demonstrated that this was due to removal of a specific growth factor, 17β-estradiol, from its cellular target, the estrogen receptor (ER) [17]. Clinicians now routinely use tissue ER content to individualize anti-estrogen therapy for breast cancer patients [18]. The most commonly used adjuvant therapy for the treatment and prevention of estrogen receptor–positive (ER+) breast cancer is Tamoxifen, which results in a 30% reduction in annual breast cancer death compared with placebo [18]. The main anti-estrogenic active metabolite of Tamoxifen is endoxifen, and the key liver enzyme catalyzing the conversion from intermediates to endoxifen is CYP2D6 [19]. Approximately 7% of the population are homozygous for an inactive allele (*4 is the most common variant allele among individuals of European descent, whereas *10 is the most common allele among those of Asian descent); [20] based on the genotype, subjects are categorized as EM, PM, or UM. There is growing clinical evidence of the pharmacogenetic effect of *CYP2D6* variants on tamoxifen treatment outcomes, with PM women showing a significantly shorter time to recurrence [21,22]. Punglia et al. estimated that the 5-year disease-free survival of tamoxifen-treated patients with no mutations (wt/wt) was 83.9%, which is similar to the 84.0% of genotypically unselected patients who were

treated with aromatase inhibitors [23]. Chapter 17 discusses these issues in detail.

Proton-pump inhibitors (PPIs) are among the most extensively used drugs in the world. In EMs, CYP2C19 is responsible for >80% of the metabolism of omeprazole, lansoprazole, and pantoprazole [24], with CYP3A4 undertaking most of the remaining metabolism [25,26]. The metabolites produced are inactive. Eight variants (*2–*8, *17) in the *CYP2C19* gene have now been associated with reduced enzyme activity *in vivo*, largely because of the production of inactive enzyme proteins [27,28]. Standard recommended doses of any of these PPIs might not provide sufficient acid suppression in homozygous EMs, suggesting that an increase in dose might be required in this group. Indeed, one study showed that increasing the lansoprazole 30 mg dose from once daily to four times daily in homozygous EMs leads to an increase in mean 24 h intragastric pH from 4.5 to 7.0 [29]. (see Chapter 17)

1.3.2 Predicting Drug Dosage

Warfarin pharmacogenomics offers the best example of genetic variation influencing drug dosage that is validated across different racial/ethnic/geographic groups (see Chapter 24). The effect on warfarin dose requirements of variants of cytochrome P450 2C9 (CYP2C9—the principal enzyme in warfarin metabolism) and vitamin K epoxide reductase complex 1 (VKORC1—the target protein inhibited by warfarin to produce therapeutic anticoagulation) has been extensively studied, with 2–10% and 10–25% of the variance in dose independently accounted for by the *CYP2C9* and *VKORC1* genotype, respectively [30–32]. A pharmacogenetic warfarin dose refinement algorithm based on clinical information, INR, and genetic factors was shown to explain at least 69.1% of therapeutic dose variability after about one week of therapy [33]. Subsequently, an algorithm produced by the International Warfarin Pharmacogenomics Consortium showed that genotype-guided therapy exhibits the greatest benefits in patients, ultimately requiring 3 mg/d or less (33.9% of cohort) or 7 mg/d or more (12.4% of cohort). However, the first prospective, randomized controlled trial to compare genotype-guided dosing to "standard" empirical dosing has produced a negative result [34]. This has led to caution about warfarin genetic testing:

> *"Testing could result in net harm to patients. For example, a result of "wild type" from the genetics laboratory may impart an unjustified sense of security to the clinician, leading to inappropriately high initial warfarin doses, an unsafe delay in early follow-up INR measurements for a patient new to warfarin, or an inappropriately long interval between INR checks for warfarin-experienced patients. Similarly, a genotype that suggests that a patient needs low doses may lead to initial underdosing with resultant subtherapeutic INR, exposing the patient to an avoidable risk of thrombosis. Any such unintended adverse effects from genetic testing would need to be subtracted from any hypothetical benefits in a proper cost-effectiveness calculation" [35].*

1.3.3 Predicting Drug Toxicity

The association of prolonged muscle paralysis and apnea by the muscle relaxant succinylcholine with atypical butyrylcholinesterase (pseudocholinesterase) is a well-known highly penetrant monogenic pharmacogenomic trait (see Chapters 18 and 35). Four percent of Caucasians have at least one abnormal *BCHE* allele that results in an enzyme with either altered affinity (atypical (A), fluoride (F), and some silent (S) variants) or decreased quantity (e.g., K, J, and some S variants). Only 1 in 3500, or ~0.03%, have genotypes (AA, AK/AK, A/AK, SS, S/AK, and AS) that result in BChE activity that is low enough to prolong apnea with a muscle relaxant. Screening for the five most common mutations (fluoride-1, fluoride-2, K variant, dibucaine, and silent-1) identifies 85% of individuals with a genetic basis for prolonged apnea with neuromuscular blockers [36].

Isoniazid is an effective treatment for tuberculosis, but is limited by peripheral neuropathy. It was observed that individuals at greatest risk of peripheral neuropathy excrete more isoniazid unchanged in the urine and a reduced amount of acetylisoniazid [11], suggesting a putative role for a drug-metabolizing enzyme. The enzyme responsible for isoniazid acetylation is N-acetyltransferase type 2 (NAT2), and variation in the gene affects acetylation capacity, resulting in a bimodal distribution of isoniazid plasma concentrations [37] attributable to a single-gene effect. NAT2 also acetylates a number of other drugs, including hydralazine, procainamide, dapsone, and some sulfonamide derivatives. Slow acetylator status is associated with a higher risk of peripheral neuropathy with isoniazid and a lupus-like reaction with hydralazine [38] (see Chapters 17 and 36).

Carbamazepine is a widely used drug for the treatment of epilepsy, bipolar disorder, trigeminal neuralgia, and chronic pain. A rare serious adverse effect of carbamazepine is Stevens-Johnson syndrome/toxic epidermal necrolysis (SJS/TEN), which is associated with 30% mortality [39,40]. A case–control study conducted on Han Chinese residing in Taiwan first identified HLA-B*15:02 as the genetic marker for CBZ-induced SJS/TEN [41]. HLA-B*15:02 is largely absent in individuals not of Asian origin (e.g., Caucasians, African Americans, Hispanics, and Native Americans). Although no published data have confirmed the HLA-B*15:02–SJS/TEN association, the higher prevalence of this variant in Asian populations [42] resulted in the Food and Drug Administration's decision to recommend testing in patients of Asian origin. (see Chapters 21).

Thiopurine methyltransferase (TPMT) is a cytosolic drug–metabolizing enzyme that probably makes the strongest case of all for prospective pharmacogenetic testing

(Figure 1.3). TPMT catalyzes the S-methylation of 6-mercaptopurine, azathioprine, and thioguanine to inactivate the thiopurine drugs, which are used for the treatment of leukemia and autoimmune diseases. More than 20 variant alleles of the TPMT gene have been identified, among which TPMT*2, TPMT*3A, and TPMT*3C are defective alleles that produce poor enzymatic activities. Inherited TPMT deficiency predisposes to myelosuppression with both azathioprine and its initial product, 6-mercaptopurine (6-MP) [43]. In Caucasians, a trimodal distribution exists, with 0.3–0.6% having low or undetectable activity (homozygotes for the variant allele, e.g., *3A/*3A), 10% having intermediate activity (heterozygotes, e.g., TPMT*1/*3A), and the remaining 90% having high (normal) activity (homozygotes for wild-type alleles, e.g., *1/*1) [44,45]. TPMT*3A is the most common variant in Caucasians [46], whereas *3C is the most frequent mutation in those of African [47] or East or Southeast Asian origin [48,49]. One study showed that screening for TPMT*2 and *3A – *3D plus sequencing of the open reading frame predicts low, intermediate, or normal/high TPMT activity phenotype in 98% of cases [45] (see Chapter 17).

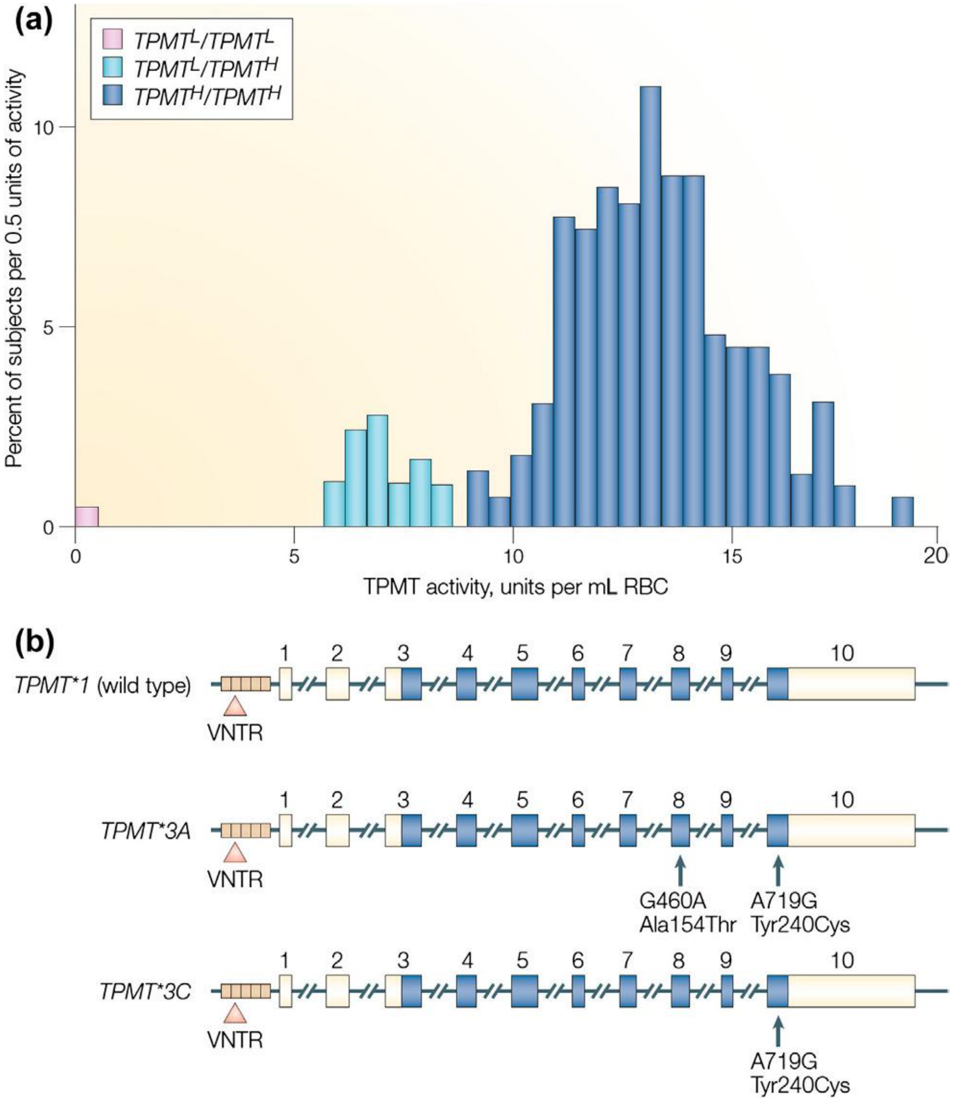

FIGURE 1.3 Classic pharmacogenetic traits: thiopurine S-methyltransferase polymorphism. (a) Activity of the drug-metabolizing enzyme thiopurine S-methyltransferase (TPMT) in red blood cells from 298 randomly selected Caucasian blood donors. Presumed genotypes for the TPMT genetic polymorphism are also indicated. $TPMT^L$ and $TPMT^H$ are designations for alleles resulting in "low" and "high" activity, respectively. These allele designations were used before the molecular basis for the polymorphism was understood. (b) TPMT alleles. TPMT*1 is the most common allele (wild-type) generally; TPMT*3A, with two nonsynonymous-coding SNPs, is the most common variant allele in Caucasian subjects; and TPMT*3C is the most common variant allele in East Asian subjects [46]. Rectangles represent exons, with blue areas representing the open reading frame. Arrows indicate two SNPs, as well as a polymorphic variable number of tandem repeats (VNTR) in the promoter. *Source: (a) Modified with permission from* [44], *© University of Chicago Press (1980). Reprinted with permission from* National Review of Drug Discovery [15].

Uridine diphosphate glucuronosyltransferase 1A1 (UGT1A1) belongs to the uridine diphosphate glucuronosyltransferase superfamily, and it is the first pharmacogenetic test to achieve FDA approval for use in conjunction with a specific drug (irinotecan). The activity of UGT1A1 varies widely, with an in vitro study demonstrating a 17-fold variation in SN-38 glucuronidation [50]. High levels of SN-38 lead to severe side effects, including severe myelosuppression in 15–20% and severe delayed-type diarrhea in 20–25% of patients receiving irinotecan. UGT1A1*28 is the variant most frequently implicated in defective SN-38 (the active metabolite of irinotecan) glucuronidation, and it occurs commonly; the homozygous genotype is found in 5–15% of Europeans, 10–25% of Africans and South Asians, and 1–5% of Southeast Asians and Pacific Islanders [51]. The FDA has recommended that patients be genotyped for the UGT1A1*28 polymorphism and that the dose be adjusted accordingly before irinotecan treatment (see Chapter 17).

1.4 GENOME-WIDE ASSOCIATION STUDIES IN PHARMACOGENOMICS

Candidate gene approaches have resulted primarily in the identification of genetic variants in drug-metabolizing genes with large effects on toxicity or response. Genome-wide association studies (GWAS) have identified a number of common single-nucleotide polymorphisms (SNPs) associated with drug efficacy and safety, with the majority of the signals in unanticipated genes or in loci of unknown functional relevance. When considering all of the GWAS cataloged in the U.S. National Human Genome Research Institute, pharmacogenomics studies are sevenfold more likely to achieve odds ratios (ORs) >3.0 compared with common disease GWAS [52]. Two major reasons have been proposed for the large effect of single-nucleotide polymorphisms (SNPs) identified in pharmacogenomic studies [52]. First, until recently humans had not been exposed to synthetic drugs—modern drugs with the longest histories have been available for only a little over 100 years—and so there has been little negative evolutionary pressure for drug use, allowing polymorphisms to become relatively common in human populations. Second, there might be a large interplay between the gene and the drug effect. For example, carbamazepine-induced severe skin-adverse reaction [41] manifests only if an individual takes the drug. The size of the subject population required to obtain significantly different allele frequencies in individuals with the phenotype versus those without might be expected to be relatively small [52]. Table 1.2 summarizes the major findings from pharmacogenomic GWAS, highlighting some of the novel pathways identified using this approach.

TABLE 1.2 Associations Between SNPs and Drug Toxicity/Efficacy From Genome Wide Association Studies

Drug	Response/toxicity	Lowest p-value	Gene	Reference
Adverse Reaction				
Ximelagatran	Drug-induced liver injury	6.0×10^{-6}	*HLA-DRB1*0701;DQA1*0201*	[53]

1.5 THE ROAD TO PERSONALIZATION AND STRATIFICATION

Accelerated developments in genomics and other high-throughput technologies, cellular programming, and stem cells are having a major impact not only in drug development but also in the practice of medicine. The current clinical drug development process is fraught with uncertainty, with up to 90% of human trials on new drugs failing to achieve registration [86]. It is evident that identifying patients who are probable nonresponders to the standard dosing regimen and/or patients with an increased risk of adverse drug reactions will have a positive impact on the benefit–risk ratio of a drug and consequently lead to effective drug development.

1.6 PHARMACOGENETIC BIOMARKERS AND COMPANION DIAGNOSTICS

In order to translate pharmacogenomic discoveries to the clinical setting, a biomarker or a diagnostic test is essential.

BOX 1.2 Therapeutic Continuum

Empirical Medicine

Current clinical practice can be termed “all comer,” or “empirical,” medicine, where the basis of treatment is derived not from the scientific method but rather from practical experience or observation, such as clinical trials or meta-analysis. Empirical medicine relies on the assumption that population-based response data from clinical trials can be applied to the individual patient, and in many cases this is reasonable where the drug works for most patients (e.g., NSAIDs). However, when drugs are effective in only a subset of patients (e.g., antidepressants) and no method is available to identify these patients, treatment is administered to everyone with the diagnosis.

Individualized or Personalized Medicine

At the other end of the continuum is individualized or personalized medicine, where therapy is matched specifically to an individual patient and may not work in other patients. In contrast to empirical medicine, this generally promises to result in both higher-quality treatment for individual patients and lower healthcare costs since patients will be offered only therapies that are effective for them and nonsafe or noneffective treatments will be avoided.

Most advances in individualized medicine come from oncology. For example, the cancer vaccine Oncophage, which is currently in development, utilizes a unique “signature” obtained from tumor cells taken from a patient during surgery [87] for the production of a vaccine that is administered to the patient post-surgery. This vaccine, which is only suitable for the patient from whom it is derived, stimulates an immune response that attacks tumor cells remaining after surgery in the body.

Stem-cell–based therapies could also potentially increase the role of individualized medicine in the future. Cellular reprogramming is technically laborious and can take several weeks, which limits the application of this technology [88]. The recent demonstration that various solid tumors arise and are maintained by cancer stem cells (CSC) advocates the development of treatments targeting CSCs in order to enhance cancer therapy effectiveness and reduce tumor relapse [89]. Despite the promise of induced pluripotent stem (iPS) cells, several limitations currently exist — reactivation of the oncogene c-Myc, immune rejection, inefficiency of reprogramming, epigenetic memory, and so forth [89]. Less extreme examples of patient matching to a medicine include therapies for which some form of marker is available to indicate that a given patient is likely to show a response to the therapy.

Stratified Medicine

Current pharmacological treatment, or empirical treatment, is based on a stepped or adaptive model of care where tailoring of treatment depends on the patient’s actual response to previously offered treatment, with a sequence of interventions (which may differ in intensity, duration, cost, or complexity) being offered to those who have not responded sufficiently [90,91]. Stratified medicine adds a step to traditional clinical practice, and instead of proceeding to treat all patients, it uses baseline information about a patient’s likely response to formulate treatment decisions. In stratified medicine, treatment (including pharmacological and nonpharmacological interventions) is targeted to specific subgroups of patients who share certain biological or risk characteristics, thereby generating more favorable benefit–risk profiles for the therapeutics than with a traditional empirical “all-comers” or empirical approach [92,93].

Stratified medicine is already practiced in several contexts. Examples in common clinical practice include the decision to give lipid-lowering therapy to people above a certain threshold of cardiovascular risk estimated from a prognostic model; the use of bisphosphonates for women over the age of 50 considered to have an increased risk of vertebral fractures; the targeting of primary care management of back pain; antibiotics matched to specific resistant infections; HIV therapies tailored to the viral variant present; a positive HER-2 status in breast cancer; and the use of trastuzumab or imatinib in patients with chronic myeloid leukemia targeted to those with the BCR-ABL mutation; and gefitinib used to treat pulmonary adenocarcinoma in patients with epidermal growth factor receptor mutations [94,95]. Individuals of African ancestry tend to have a salt-sensitive type of hypertension that is responsive to diuretics or calcium channel blockers, while Europeans are more responsive to ACE inhibitors or angiotensin receptor blockers; initial management of hypertension uses a stratified approach based on ethnicity [96,97]. Stratified medicine can therefore increase medical value both for treated patients and for untreated patients, who can more rapidly seek alternative therapies that may be more effective.

The transition from empirical medicine to stratified medicine occurs when biomarkers are identified that can classify patients based on therapeutic efficacy or adverse effects. This is the stratification step that occurs after a disease diagnosis is made and treatment options are considered. While stratified medicine lies in between empirical and individualized medicine in the therapeutic continuum (see Figure 1.4) [92], sometimes, the stratification biomarker identifying differential response can lead to the identification of a new subtype of the index disease. This can result in the stratified medicine patient subpopulation emerging as a clinically distinct diagnosis treated empirically with the stratification biomarker now used as a diagnostic test. For example, in breast cancer expression of the receptor tyrosine kinase HER2 characterizes the cancer type and the suitability for receiving trastuzumab (Herceptin, Genentech) as an adjuvant therapy [95].

Pharmacogenomics and stratified medicine are part of the continuum of drug development and clinical implementation toward reduced dependence on “trial-and-error medicine” as well as improved efficiency and effectiveness of healthcare delivery [92,98]. Stratification represents a more targeted approach to therapy, offering the potential of greater efficacy of treatments and minimization of their side effects. For example, the 2–9% of patients who test positive for HLA-B*57:01 will not be prescribed Abacavir, leading to decreases in the requirement to treat illness arising from adverse drug reactions, which could be of great benefit to healthcare systems in limiting costs. Another example is the 55% efficacy of crizotinib in patients with locally advanced or metastatic non-small cell lung cancer (NSCLC) that is anaplastic lymphoma kinase– (ALK-) positive, compared to the approximately 5% overall response.

Not surprisingly, pharmacogenomic discoveries are often followed by discussions about clinical implementation. The cost-effectiveness of stratification will depend on several factors, including the cost of testing the patient population, the proportion of "responders," and the (saved) costs of treating nonresponders, which will be greater as the health consequences of any adverse reaction grow. For a particular disease, a stratified medicine strategy can emerge only when certain conditions exist, as shown in Figure 1.5.

More importantly, it is essential that two conditions be met: the presence of multiple treatment options for the disease with heterogenous responses and a logistically and medically acceptable biomarker that can stratify different treatment options [92]. If no biomarker exists, stratified medicine will not emerge because a therapy and a patient subpopulation cannot be linked. However, identification of markers associated with drug response does not always equate to clinically useful predictors. The translation and acceptance of novel genetic and genomic biomarkers in clinical practice must be dependent upon the evidence associated with individual markers to be useful for a particular purpose.

A biomarker is a characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacological responses to a therapeutic intervention [99]. A pharmacogenomic biomarker is any molecular "barcode" obtained by analysis of mRNA, DNA, protein, or circulating cells that may be used to stratify patients for treatment benefit within clinical trials, to prognosticate patient outcome, or to predict and/or monitor response to therapy.

The result of the pharmacogenomic biomarker assay can determine (1) whether a patient is suitable for treatment with a particular drug (by stratification markers), (2) the most effective dose for the patient (by efficacy markers), (3) the underlying susceptibility of a patient to a particular side effect or group of side effects (by toxicity markers), or (4) the course and effectiveness end point of a therapy (by surrogate end point markers) [100–102]. The goal of these tests is to change the benefit–risk ratio to a degree that would justify the cost and inconvenience of the test (Figure 1.6).

While the FDA website lists ~122 different biomarkers such as gene variants, functional deficiencies, expression changes, and chromosomal abnormalities (see Table 1.1), pharmacogenomic information with action-oriented instructions for physicians and patients is presently limited to approximately 25–30 therapeutic agents, depending on healthcare system and country.

Pharmaceutical companies are increasingly looking to develop a drug and diagnostic test (companion diagnostic, or CDx) simultaneously (drug-diagnostic/co-development) to stratify the patient population for treatment [103]. There are multiple technology platforms that can aid the discovery of companion diagnostics; these are summarized in Table 1.3. Until recently, pharmaceutical companies were focused on "blockbusters" and were unsupportive of "companion diagnostics," thinking that these would divide patient populations into smaller groups and contract their markets. Moreover, early knowledge of relevant predictive biomarkers has historically been the exception rather than the rule in drug development, and the potential for stratified medicine so far has not been fully realized [104,105]. Following the success of two targeted anticancer drugs—trastuzumab (Herceptin; Roche/Genentech) and imatinib (Gleevec;

TABLE 1.3 Biomarker Discovery Technology Platforms and Potential for Companion Diagnostic Utility

Technology platform	Examples	Characteristics for assay development	Clinical utility
Mass spectrometry	Metabolomics	• Low throughput • Expensive • No automation	• Low throughput • Costly
Protein recognition assays (immunoassays)	Immunoassays, aptamers	• High sensitivity • Rapid • High throughput	Limited to certain therapeutic areas
Imaging	Microscopy, computed tomography (CT), Magnetic resonance tomography (MRT), Near-infrared spectroscopy (NIRS), photo-electron tomography (PET)		Useful as prognostic biomarker of drug impact on tumor size as opposed to a metric of tumor shrinkage
Polymerase chain reaction (PCR) as an assay	Allele-specific PCR, qPCR, digital PCR (dPCR)	• Requires ≥ 1 μg genomic DNA • Long assay development time	• Standard for many assays • Useful as setup for sequencing • Low cost • High throughput
Next-generation (NGS) sequencing	Whole genome, targeted, hybridization selection, amplicon sequencing	• Require nanogram amounts of DNA • Faster assay development time • Low cost/base • High sensitivity • High throughput • Flexible to quickly incorporate changes	• High throughput • Multiplex capability • Infinite number of regions to target in single run • Single run can provide data useful in heterogeneous and complex oncology diseases
Anatomic histopathology	Immunohistochemistry (IHC), in situ hybridization (ISH), quantum dots, fluorescence, resonance, or radioactive labeling; multiplex IHC	• Allows specific target localization provided antibodies have high specificity • Ideal way to detect protein pathway activation • Long assay development time	• Limited multiplex capabilities

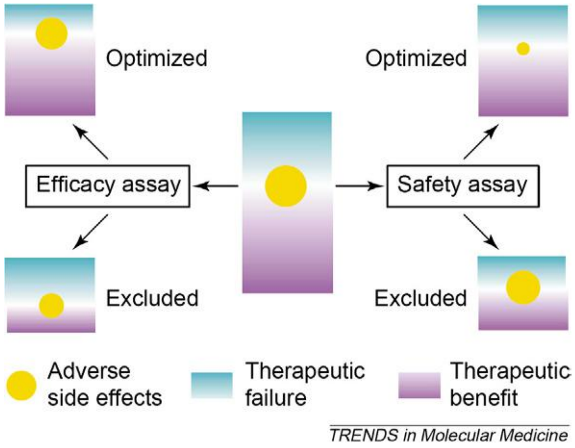

FIGURE 1.6 Clinical application of pharmacogenetic tests. In the general population (center) some individuals taking a particular drug will derive therapeutic benefit (purple) and some will not (blue). Also, some individuals will have a characteristic adverse side effect (yellow). Pharmacogenetic assays will determine whether a patient is more or less well suited to the particular drug based on results from a genotyping assay. In some cases, there might be both efficacy- and safety-based assays. *Source: Reprinted with permission from Elsevier: Trends in Molecular Medicine* [1].

Novartis)—which combined a drug with a companion diagnostic to select or exclude patients for treatment, there is now a growing list of FDA-approved therapies and their companion diagnostics (Table 1.4). Additionally, CDxs can make drug development more efficient and effective because they can reduce costs through preselected (smaller) patient populations, improve the chances of approval, and significantly increase market uptake [104,105]. In July 2011, the FDA released draft guidelines that require CDx tests to be approved simultaneously with their accompanying therapies if necessary for the safe and effective use of a medication. Developing CDx tests in conjunction with therapeutics allows the design of better clinical trials and eventually better implementation of pharmacogenomics testing [106].

1.6.1 Evaluating Pharmacogenomic Biomarkers/CDx for Clinical Use

Recently Love et al. [107] proposed seven stages of CDx co-development, providing an overall depiction of the key questions to address at each phase of CDx development.

Defining an unmet need. What is the clinical problem to be solved? How the test and therapeutic contribute to the solution should be articulated in a target product profile (TPP) for both the test and the therapeutic. Moreover, it is of crucial importance to establish criteria by which success for both will be measured in terms of sufficiently fulfilling the TPP.

Biomarker discovery. What is available to solve the problem? During this stage one must characterize the information provided by a biomarker (or multiple biomarkers), determine the appropriate platform on which to identify the analyte, recognizing that it could be *in vivo* imaging or an in vitro analyte and selecting the appropriate body "compartment" from which to extract the information (e.g., sample type).

Technical assay validation: Can you reliably measure the biomarker(s)? The key deliverable at this stage is demonstrating that the test and any associated instrumentation are capable of reproducibly measuring the biomarker(s) in relevant sample type(s).

Clinical validation: Is the test informative and relevant in the clinical condition/disease? At this stage, the test is evaluated to determine if its performance displays an appropriate degree of reproducibility (precision and accuracy), sensitivity, specificity, and linearity over the range of possible test results in light of the clinical condition for the drug's intended use in the TPP.

Clinical utility. Does the test provide actionable information regarding the condition/disease? Data obtained during this stage demonstrate how the positive and negative predictive value provided by the test enables improved treatment decision making, typically by further refining the characterization of the patient's condition/disease beyond what is possible with the current standard of care.

Medical utility. Is the information used to make a treatment decision that improves an outcome? At this stage, the test typically enters routine usage by medical professionals, who use the information obtained from it to make treatment decisions. The test is often incorporated into treatment guidelines and demonstrates an impact on treatment outcomes.

Commercial adoption. Is the test and associated treatment established as a standard of care and appropriately reimbursed? In this final stage, the test-and-treatment approach is fully integrated into routine patient care and often data exist suggesting or demonstrating a health/economic benefit from the use of this approach.

TABLE 1.4 FDA-Approved Drugs with Their Companion Diagnostics Tests

Drug	Gene	CDx	Developer	Indication
Trastuzumab	Her2	Inform Her2/Neu	Roche (Ventana Medical Systems)	Breast carcinoma
		PathVysion Her2 DNA Probe Kit	Abbott (Abbott Molecular)	
		Pathway ANTI-Her2/NEU (4B5)	Roche (Ventana Medical Systems)	
		InSite Her2/NEU Kit	Biogenex Laboratories	
		SPOT-Light Her2 CISH Kit	Life Technologies (Thermo Fisher Scientific)	
		Bond Oracle Her2 IHC System	Leica Biosystems	
		Her2 CISH PharmDx Kit	Agilent Technologies (Dako)	
		INFORM Her2 DUAL ISH DNA Probe Cocktail	Roche (Ventana Medical Systems)	
		Herceptest™	Agilent Technologies (Dako)	
		Her2 FISH PharmDx Kit	Agilent Technologies (Dako)	
Cetuximab, Panitumumab	EGFR	DAKO EGFR PharmDx Kit	Agilent Technologies (Dako)	Colorectal cancer
Cetuximab	KRAS	Therascreen KRAS RGQ PCR Kit	Qiagen	
Imatinib mesylate	c-kit protein/CD 117	DAKO C-KIT PharmDx	Agilent Technologies (Dako)	Gastrointestinal stromal tumors (GIST)
Crizotinib	ALK	VYSIS ALK Break Apart FISH Probe Kit	Abbott (Abbott Molecular)	Non-small-cell lung cancer (NSCLC)
Erlotinib	EGFR	COBAS EGFR Mutation Test	Roche Molecular Systems	
Afatinib	EGFR	Therascreen EGFR RGQ PCR Kit	Qiagen	
Vemurafenib	BRAF	COBAS 4800 BRAF V600 Mutation Test	Roche Molecular Systems	Melanoma
Dabrafenib, Tramatenib	BRAF	THxID BRAF	bioMérieux	

The criteria for evaluating genetic tests are summarized by the four components of the ACCE analytic framework: analytic validity, clinical validity, clinical utility, and associated ethical, legal, and social implications [108]. Clinical validity refers to a test's ability to detect or predict the clinical disorder or phenotype associated with the genotype. Because most drug response phenotypes are multifactorial, it is not always easy to achieve the high clinical validity for pharmacogenetic testing that is often achieved with molecular testing for Mendelian disorders. Consequently, the positive predictive value of many pharmacogenetic assays can be low. Clinical utility of a test is a widely used measure of its usefulness in the clinic and of the changes in health outcomes that result. (See Figure 1.5.) However, given the multidimensional nature of this kind of measurement, there is rarely consensus as to its precise definition or how to adequately demonstrate it, particularly with regard to personalized medicine and pharmacogenetics [109]. Moreover, differences in regulators' requirements for clinical evidence for diagnostics vary between regions. The current FDA approach to diagnostics is generally more rigorous in terms of the clinical evidence required, while in Europe diagnostics manufacturers must satisfy essential safety and analytical performance requirements but are not required to establish that the diagnostic has an impact on clinical outcomes to obtain a CE marking [110].

The common benchmark for interventional evidence in medicine is an RCT (see Chapter 15), yet these are often resource-prohibitive for testing pharmacogenetic hypotheses and may be unethical regarding strong associations of severe adverse effects associated with high-risk genotypes. There is growing debate over and interest in the most appropriate study design that would provide evidence to accelerate translation of pharmacogenomic discoveries [109,111,112]. A key challenge in deciding which approach is most appropriate to establish the clinical utility of a new biomarker, is that genetic or other biomarkers often explain only a fraction of the observed outcome; other factors, including environment account for the remaining. RCTs, by definition, control all factors that could influence outcome, resulting in an artificially increased level of the standard of care. Thus they may dilute the effect of using a biomarker to guide decision making. Adaptive clinical trial designs are a modification of the standard RCT design for targeted therapeutics. The European Medicines Agency (EMA) in 2007and the FDA in 2010 published guidance on appropriate adaptive-trial conduct [113]. The use of retrospective and prospective case–control and cohort studies based on large databases has advantages over RCTs. The recent FDA updated drug label for carbamazepine regarding possible susceptibility to severe cutaneous reaction among Asian-ancestry carriers of the HLA-B*15:02 allele was based on retrospective observational data. Because of the low specificity of the test (i.e., most HLA-B*15:02 carriers will not develop an adverse event), it would be impossible (aside from being highly unethical) to study this marker in a RCT [112]. Abacavir-associated hypersensitivity reaction was observed in the drug development and post-approval stages, but it was a combination of retrospective and prospective studies that led to the identification of HLA-B*57:01 as a significant risk factor for this condition [114]. Subsequent RCTs showed that the positive predictive value of HLA-B*57:01 carriage for the development of abacavir-associated hypersensitivity reaction was ~50%, suggesting that the HLA-B*57:01 allotype is necessary but not sufficient for it [115]. Retrospective analyses have also proven useful in defining distinct patient subgroups that benefit preferentially from targeted therapeutic approaches [116–118].

1.7 ECONOMIC CHALLENGES

Healthcare expenditure in developed nations has been increasing faster than gross domestic product (GDP) over the past 40 years, mainly because of increasing per capita costs [119]. However, despite the success stories, pharmacogenomics has had limited impact on clinical practice to date. The list of FDA-approved companion diagnostics is still relatively small, with only 10% of currently marketed drugs having any pharmacogenomic information on the label, and the FDA currently mandates testing only for trastuzumab, cetuximab, and panitumumab.

There are significant clinical, financial, and ethical barriers to the successful implementation of pharmacogenomics. A significant trend in healthcare discussions is the focus on clinical utility and comparative effectiveness. The increasing emphasis on demonstrated therapeutic utility—"personal utility" in particular—will continue to have significant impact on clinical development strategies. At present, the extent of scientific knowledge related to the average safety and efficacy of potential drugs is typically much greater than knowledge about the underlying structure of drug responses in patient subpopulations and knowledge about the existence of predictive biomarkers to identify the most appropriate patient subpopulations for treatment.

However, utility can mean different things to the various stakeholders in the healthcare continuum. Traditionally, clinical development establishes the benefit–risk profile in order to support registration of a new treatment. Today, there is increased pressure to use clinical trials to produce evidence of relative efficacy and comparative effectiveness as compared with alternative courses of therapy [120]. Even with FDA-approved biomarker tests that appear to be clinically useful, lingering questions persist regarding their linkage to health outcomes [121].

Another noteworthy development is the role of healthcare payers in promoting evidence gathering to support the use of pharmacogenomics to inform treatment decisions [122]. Maintaining incentives for all stakeholders is not straightforward:

> *"Reimbursement frameworks that are dynamically linked, both initially and post-approval, to the patient population that benefits, rather than the patient population that is treated, provide incentives for co-developers to seek patient subpopulations that respond more effectively to treatment. Conversely, perpetuating the current reimbursement frameworks that are linked to existing, lower-efficacy treatment and diagnostic regimens discourages the development of stratified medicine" [123].*

According to a report issued by the Academy of Medical Sciences [110], for stratified medicine to become the standard in disease management the following requirements must be fulfilled:

Continued research to understand the genetic and molecular basis of disease.
Development and use of increasingly sophisticated and powerful informatics technology.
Improvement and standardization of clinical data collection and linkage with genomic and other databases.
Increased collection of tissues for biomarker research and evaluation, and their organization in national and international biobanks.
Greater efficiency and productivity in the development of therapeutics and diagnostics.
Flexible and novel approaches to regulatory assessments of innovative stratified medicine products.
Improved flexibility in pricing for stratified medicine products—for both diagnostic and associated therapy—to ensure cost-effectiveness for payers and encouragement of innovation.

Large, accessible datasets of patient information that employ the appropriate safeguards are essential to

BOX 1.3 Key Factors Affecting the Economic Value of Stratified Medicine

It is unclear whether a stratified medicine approach will enhance or reduce the economic value of a particular drug. After the introduction of a new therapeutic and its companion diagnostic, it is likely that a new equilibrium will initially be established that reduces patient populations because of diagnostic exclusion, enhanced efficacy, and safety. Market share will increase as the therapy becomes the preferred treatment [92]. In time, however, further market expansion will occur as underserved patients enter the market encouraged by the greater certainty of outcome should they qualify, and as long-term compliance improves [92] (see Figure 1.7).

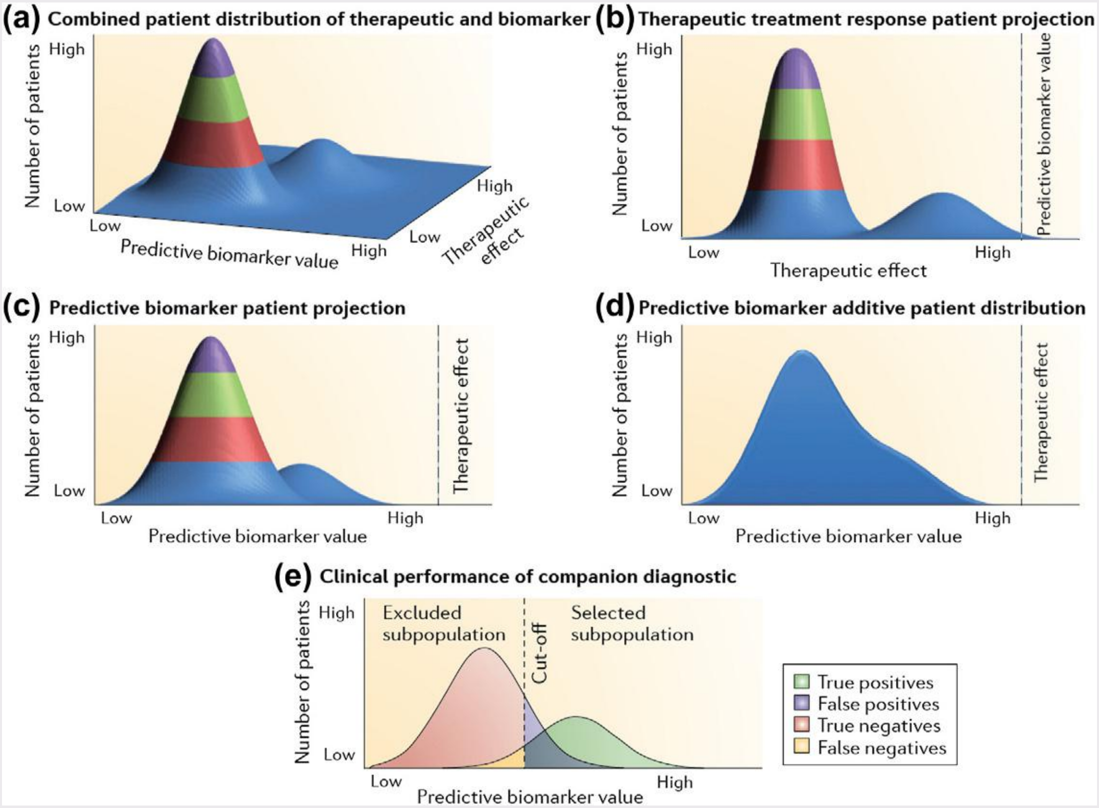

FIGURE 1.7 Key factors affecting the economic value of stratified medicine. Therapeutic effect is defined as the observed benefit of the treatment in patients. For traditional medicine this is usually simply stated as the mean benefit observed in the treated population compared to a placebo-treated or comparator-treated population. For stratified medicine this becomes more refined, as the treated population may refer to an all-comers–treated population, a biomarker-selected–treated population, or the underlying true treatment responders. The prevalence of the predictive biomarker is the fraction of the patient population that is selected by it and obviously has a direct and substantial effect on the number of patients who are subsequently treated. Notably, the selected population may be the converse of the patient population possessing the actual analyte measured. In addition, for a predictive biomarker with a continuous value, prevalence depends on the cut-off value selected.The clinical performance of the companion diagnostic is the ability of the test developed for the predictive biomarker (the companion diagnostic) to distinguish treatment responders from nonresponders. It is related to the combination of a test's sensitivity and specificity as well as negative and positive predictive values. It is important to recognize that most companion diagnostics perform substantially below perfect separation (with 100% values for all four metrics). The clinical performance of the companion diagnostic not only directly affects the number of patients who are potentially eligible for treatment but also affects the net benefit enrichment achieved, as patients who are selected by the companion diagnostic and are nonresponders also receive treatment, thereby reducing the observed average response. This has an impact on the price, market share, and speed of clinical adoption of the treatment.The patient population distributions for the therapeutic and the predictive biomarker usually separate imperfectly, as shown in part (a). Characterizing these distributions and their intersections provides much of the power and presents much of the development challenge of a stratified medicine approach. (a) Hypothetical patient distribution plotted against both therapeutic effect and a continuous-value predictive biomarker, illustrating a 30% high-responder subpopulation and a 70% low- or nonresponder subpopulation. (b) Projection of therapeutic effect only, showing a clean bimodal patient separation. (c) Two-dimensional projection of only the predictive biomarker value, with the therapeutic responder status preserved, allowing a nonadditive plot. Notably, two overlapping distributions result because clinical performance is less than perfect. (d) Observed patient distribution with a predictive biomarker, with no information on therapeutic effect. (e) Dichotomization of a continuous predictive biomarker into a companion diagnostic test to select a patient subpopulation for treatment. Both treatment responders and nonresponders scoring higher than the cut-off value (indicated by the vertical line) are selected for treatment. This example shows a case in which 30% of the total patient population responds to treatment but the chosen cut-off value generates a companion diagnostic with 90% sensitivity, 85% specificity, 96% negative predictive value, and 73% positive predictive value that selects 38% of the patients; of these, 27%will respond and 11% will not. *Source: Reprinted with permission from Macmillan Publishers Ltd: Nature Reviews Drug Discovery. Diagnostic targets patients
Patient compliance improves
Underserved patients enter
Preferred therapy for targeted patients
Market size (units)
Market share (%)

FIGURE 1.8 Potential effects of stratified medicine on the economic value of therapies. Use of a diagnostic reduces the size of the treated patient population and thereby the potential market, but enhanced efficacy/safety increases market share as the therapy becomes the preferred treatment. Further market expansion occurs as underserved patients enter the market encouraged by the greater certainty of outcome should they qualify. Improved long-term compliance through diagnostic feedback and improved tolerability can further increase market size. *Source: Reprinted with permission from Macmillan Publishers Ltd: Nature Reviews Drug Discovery. developing a stratified medicine program. They are central to the following areas: research to understand the molecular basis of disease; development of targeted interventions; effective regulation, health technology assessment, and evaluation of stratified medicine products; and stratification of treatment by physicians [110]. Co-developing a drug with a diagnostic to create a stratified medicine presents major barriers for product developers, regulators, payers, and physicians.

In reality, because of the different development timescales involved, there is little incentive for diagnostic manufacturers to co-develop a diagnostic when a drug enters its preclinical or clinical phase. On average, it takes 9–12 years to develop a drug in contrast to 3–5 years for a diagnostic. This problem is compounded by the high risk that a drug may fail to meet safety and efficacy requirements, making the associated diagnostic redundant. From an industry perspective, there is a financial "double disincentive" to stratify medicines, as manufacturers stand to pay more for R&D and see their market size shrink.

Trusheim et al. [123] performed an analysis using data from case studies in oncology and Alzheimer's disease, coupled with integrated computational modeling of clinical outcomes and developer economic value, to quantify the effects of decisions related to key issues such as the design of clinical trials. Out of the over 90 factors input into the economic models, three in particular drive economic value for stratified medicine compared to empirical medicine: relative therapeutic performance, the prevalence of the biomarker, and the biomarker's clinical performance. Enhanced therapeutic effects not only benefit patients but also enable product differentiation, market share gains, and pricing justification; each of these benefits—alone and especially in combination—return economic value to the developers of the drug and the diagnostic.

1.8 CONCLUSIONS

Clearly there is great potential for pharmacogenomics to improve the benefit–risk profile for individual patients and to improve the effectiveness of drug development. The growing number of drug labels with pharmacogenetic information, more treatment guideline recommendations based on genetics, and escalating investment in pharmacogenetics by industry, academia, governments, and institutions are all evidence that genomics is delivering on its promise, albeit slowly. There is burgeoning interest in implementing pharmacogenomic discoveries in clinical practice, and this requires cooperation from all stakeholders to develop the evidence path necessary to define utility.

Next-generation sequencing technology will make economically viable the sequencing of the entire genome of an individual (or his or her tumor) to create a personal variant file. The whole genome could ultimately function as a set of biomarkers, with sequencing of individual tumor genomes used to inform treatment decisions based on in silico models [110,124]. In the future, prescribing may depend on matching the drug to the patient using his or her stored genetic profile coupled with an improved understanding of the molecular pathway of disease, thus reducing the need for traditional companion diagnostics.

2.1 OVERVIEW OF THE CELL: ANATOMY, COMPONENTS, AND FUNCTION

Each cell is a basic building block for any organism living on Earth. These organisms are either unicellular or multicellular. In a unicellular organism, the cell or the organism performs all necessary activities required to sustain life. In a multicellular organism, various cells with specialized functions cooperate and facilitate proper functioning of the whole organism; nevertheless, each single cell in a multicellular organism is seen as the organism's basic unit of structure and function. In other words, life fundamentally occurs at the cellular level.

There are two kinds of living organisms: prokaryotes and eukaryotes. The main difference between the two is that eukaryotes have a well-defined nucleus enclosed in a membranous nuclear envelope; prokaryotes have no nucleus but a region called the nucleoid not separated from the rest of the cell. In eukaryotic cells, the region between the nucleus and the cell membrane, called the cytoplasm, is where the membrane-enclosed organelles are suspended in a semifluid medium called the cytosol. Unlike eukaryotic cells, prokaryotic cells lack most of the organelles in the cytoplasm. Prokaryotic cells are found only in the kingdom Monera (such as bacteria), while protists, fungi, plants, and animals are all eukaryotes. A detailed comparison of eukaryotic and prokaryotic cells is given in Table 2.1. The discussion of cell structure and organelle function in this chapter applies to eukaryotes.

2.1.1 Nucleus and Chromosomes

The nuclear envelope separates the two major cellular compartments: the nucleoplasm and the cytoplasm. The DNA and its associated proteins are referred to as chromatin and reside in the nucleus in eukaryotes. The chromosomes carrying the cell's genes and the machinery to express them reside inside the nucleus. Interactions with histones and other proteins fold each chromosome compactly enough to fit inside the nucleus. In higher organisms, each somatic cell contains

TABLE 2.1 Comparison of Eukaryotic and Prokaryotic Cells

Feature	Eukaryote	Prokaryote
Cell size	Typically 10–100 μm	Typically 1–10 μm
Nucleus	Present and membrane-bound	Absent but has a nucleoid region without a nuclear membrane
Other organelles	Many membrane-bound organelles	No membrane-bound ribosomes
Genetic material (DNA)	Located in the nucleus and surrounded by a nuclear membrane	Concentrated in the nucleoid
DNA arrangement	Multiple linear chromosomes	Single circular chromosome
RNA synthesis	In the nucleus	In the cytoplasm
Protein synthesis	In the cytoplasm	In the cytoplasm
Cytoplasmic structure	Cytoskeleton and cytoplasmic streaming	No cytoskeleton or cytoplasmic streaming
Organization	Often multicellular	Usually unicellular
Cell division	Mitosis and meiosis	Fission or budding

one set of chromosomes inherited from the maternal parent and a comparable set of chromosomes (homologous, or homologues) from the paternal parent. The number of chromosomes in this dual set is the diploid number. Sex cells, or gametes, which contain half the number of chromosome sets found in somatic cells, are referred to as haploid cells.

2.1.2 Membrane-Bound Organelles in Eukaryotic Cells

The endomembrane system separates the cell into different compartments, or organelles, such as the nucleus, the endoplasmic reticulum (ER), the Golgi apparatus, and lysosomes (see Table 2.2). The endomembrane system is derived from the ER and flows to the Golgi apparatus, from which lysosomes bud. The ER is a continuous system of flattened membrane sacks and tubules that is specialized for protein processing and lipid biosynthesis. The endomembrane system is important for the cell's compartmental organization to function independently and properly. Ribosomes that synthesize proteins destined for insertion into cellular membranes or for export from the cell associate with specialized regions of the ER, called the rough ER owing to the attached ribosomes.

For the most common organelles in eukaryotic cells, the structure and function of each are illustrated, using an animal cell as an example, in Figure 2.1 and Table 2.2.

2.1.3 Nonmembranous Organelles in Eukaryotic Cells

The shape of a cell is maintained by a network of fibers throughout the cytoplasm, called the cytoskeleton. In addition to structural support, the cytoskeleton functions in cell motility, such as the movement of organelles within the cell. The three fiber components of the cytoskeleton are microtubules, microfilaments, and intermediate filaments.

Microtubules are straight, hollow tubes made of tubulins. Two tubulin types, α-tubulin and β-tubulin, are similar molecular units bonded together to form the microtubule wall. Microtubules support the cell and guide the movement of organelles by providing tracks for them equipped with specialized proteins known as motor molecules. Microtubules also help in the separation of chromosomes during cell division, as discussed in later sections.

Microfilaments are solid rods built from actin molecules. Actin molecules are present in chains twisted in a helix form. Microfilaments are especially concentrated and well ordered in muscle cells and are involved in muscle cell contraction. They also play a role in supporting the cell along with the rest of the cytoskeleton.

Intermediate filaments are smaller than microtubules but larger than microfilaments in diameter. These filaments can remain in their original shape, while the microtubules and microfilaments are often disassembled and reconstructed in different parts of the cytoplasm. This suggests that they are especially important in maintaining the shape of a cell and fixing the position of certain organelles.

2.2 CELL REPRODUCTION: CELL CYCLE AND MITOSIS

Cell division may result in cell reproduction in a unicellular organism, cell growth, and development of multicellular organisms, as well as the renewal and repair of tissues in mature organisms. In a prokaryotic cell (e.g., bacterium), the type of cell division is called binary fission. Bacterial DNA is attached to the cell membrane. In preparation for

TABLE 2.2 Most Common Characteristics of Membrane-Bound Organelles in Animal Eukaryotic Cells

Organelle	Feature	Function
Nucleus	• Nuclear envelope: lipid double layer • Nuclear pores • Chromatin (mass of DNA)/chromosome (DNA double helix, visible during cell division) • Nucleolus	• Separates the nucleus's contents from the cytoplasm • Regulate nuclear transportation • Holds the cell's genetic material; human somatic cell: 46 chromosomes; sex cells: 23 chromosomes • Synthesizes the ribosome's components to be assembled in the cytoplasm
Ribosomes	• Free ribosomes suspended in cytosol • Ribosomes attached to the endoplasmic reticulum • Two ribosome types are structurally identical and functionally interchangeable	• Synthesize proteins to function within the cytosol • Synthesize proteins to be included in membranes; pack certain organelles (e.g., lysosomes) or export from cell • Interchange occurs when the cell's metabolism changes
Endoplasmic reticulum (ER)	• Rough ER (with studded ribosomes) is confluent with the nuclear outer membrane • Smooth ER (lacking ribosomes) is connected to the rough ER	• Wraps secretory proteins in the transport vesicles (e.g., glycoproteins) and produces membranes for the ER itself or other components of the endomembrane system by adding membrane proteins and phospholipids • Cell type-dependent and may function in lipid synthesis, carbohydrate metabolism, and drug detoxification.
Golgi apparatus	• Stacks of flattened membranous sacs • *cis* face[a] • *trans* face[b]	• Receives, modifies, stores, and dispatches transport vesicles (including their contents, e.g., secretory proteins from the ER) • Receives vesicles • Dispatches vesicles (ER product modification occurs during transit from the *cis* face to the *trans* face)
Lysosomes	• Membrane-bound sacs containing hydrolytic enzymes	• Digest macromolecules through phagocytosis or autophagy
Peroxisomes	• Single membrane-bound organelles containing a collection of enzymes	• Transfer hydrogen from various substrates to oxygen, producing hydrogen peroxide as a by-product. These reactions serve various metabolic functions—e.g., breakdown of fatty acids for mitochondria respiration and detoxification of alcohol in the liver
Mitochondria	• Double-membrane-bound organelles containing ribosomes and DNA • Infoldings of the inner membrane form the cristae • Number of mitochondria varies with the metabolic activity of a cell	• Convert energy for cellular respiration

[a] *One of the two poles of the Golgi apparatus located near ER and receiving the content carried by transport vesicles from ER.* [b] *The other pole of the Golgi apparatus, giving rise to vesicles that travel to other sites.*

fission, it is replicated and attached to the membrane at a site adjacent to the original copy. Continued growth of the cell membrane eventually separates the two copies of DNA, and a cell pinches in two daughter cells, each of which inherits a complete genome.

The genetic material (or genome) in a eukaryotic cell is organized into multiple chromosomes. For example, a human somatic cell has 46 chromosomes, and a reproductive cell (sperm/egg) has 23 (half of the somatic cell chromosomes). Each chromosome is organized in a long, linear

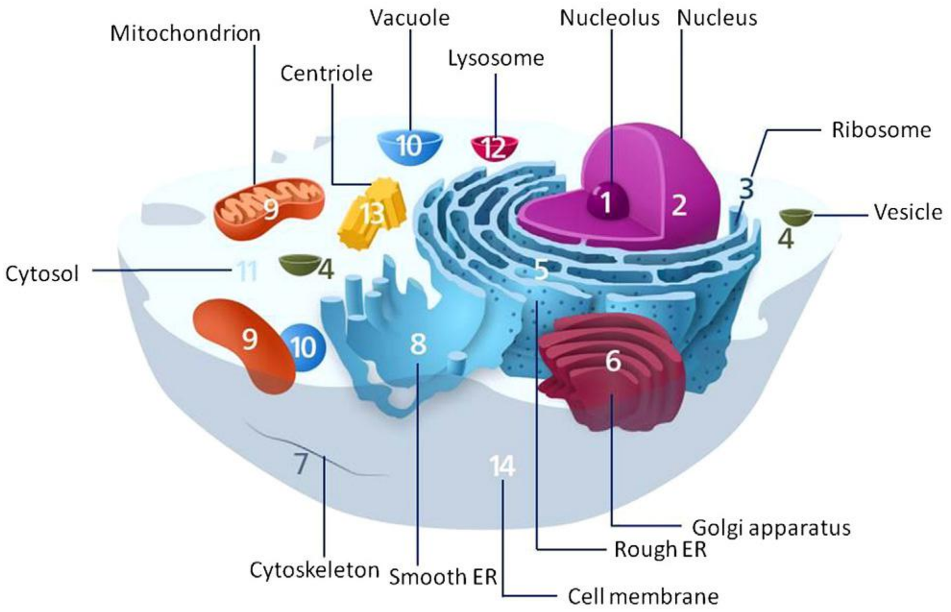

FIGURE 2.1 **The most common structures in an animal cell.** Genetic material, in the form of DNA, resides in the nucleus. Although vacuoles are included here, they generally exist in protists and plants. *Source: Reproduced from* Wikipedia Commons *(https://en.wikipedia.org/wiki/Organelle).*

DNA molecule representing a number of genes. Various proteins help to maintain the DNA structure. This DNA-protein complex is folded and coiled to produce the chromatid of a chromosome. The chromatid duplicates itself in the interphase of the cell cycle, and the two sister chromatids are held together by a specialized region called the centromere.

In a dividing cell, mitosis alternates with interphase, which takes up most of the time in each cell cycle. Interphase can be further divided into three periods of growth: the G_1 phase ("G" stands for gap, here the first gap), the S phase ("S" stands for synthesis), and the G_2 phase (the second gap). As it goes through interphase, the cell grows by synthesizing proteins and producing cytoplasmic organelles through all three subphases, while the chromosomes are duplicated only during the S phase. Once everything is prepared for cell division, the cell divides in the mitotic (or M) phase. How an animal cell completes its division during the M phase is described later.

Mitosis is conventionally separated into five stages: prophase, prometaphase, metaphase, anaphase, and telophase. During G_2 of interphase (late interphase), the nucleus, which contains one or more nucleoli, is enclosed in the nuclear envelope. Two centrosomes are present just outside of the nucleus. The replicated chromosomes (during the S phase) are still not distinguishable as loosely packed chromatin fibers. During prophase, the nucleoli disappear, and the chromatin fibers are condensed into discrete chromosomes, visible under a light microscope. Each duplicated chromosome consists of two sister chromatids held together by the centromere. As the two centrosomes move away from each other, early mitosis spindle (made of microtubules) begin to appear in the cytoplasm.

During prometaphase, the nuclear envelope is broken down, allowing the microtubule spindles to enter the nucleus and interact with the chromosomes. Some of the microtubules attach to a specific site, called the kinetochore, in the centromere region, preparing for chromosome movement. During metaphase, the chromosome's centromeres line up at the equator of the spindle, with each sister chromatid facing the spindle's opposite poles. During anaphase, the sister chromatids are separated from each other, and each one begins to move along the microtubules toward opposite poles. By the end of this phase, the two poles have identical collections of chromosomes.

At telophase, the nucleoli reappear and nuclear envelopes are reformed at the two ends of the cell, where the two sets of chromosomes have gathered. Mitosis, the division of the nucleus, is now complete and is followed immediately by cytokinesis, the division of the cytoplasm. Thereafter, two daughter cells separate shortly after the end of mitosis. In animal cells, cytokinesis starts with a cleavage furrow. Figure 2.2 describes these stages in an animal cell.

The timing and rate of cell division in different parts of an organism are deciding factors in normal growth, development, and maintenance. For example, human skin cells divide frequently, while muscle and nerve cells do not divide at all. Researchers have used cell culture to study the cell cycle and the factors that may influence it, such as nutrients, growth factors, and cell density.

Before cell division, the cell has to pass a checkpoint near the end of the G_1 phase. Cell size—more precisely, the cell's cytoplasmic volume-to-genome ratio—must reach a certain level to pass this checkpoint before DNA synthesis occurs at the S phase. Other environmental and

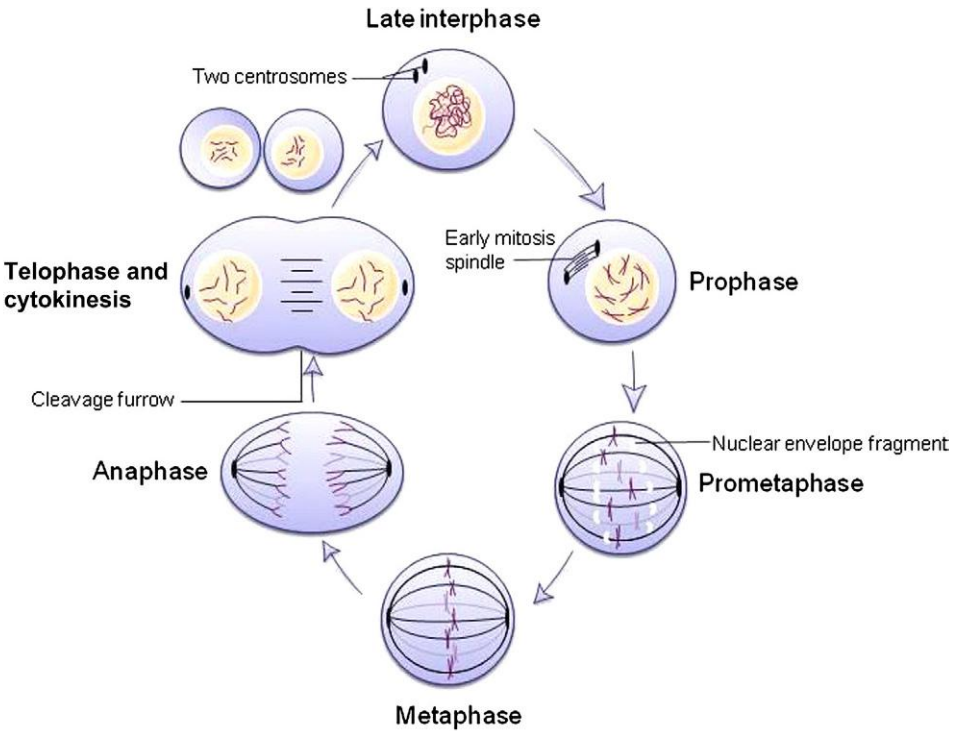

FIGURE 2.2 **Cell division—mitosis in an animal cell.** In this example, only seven chromosomes are shown.

developmental conditions must also be fulfilled to eventually initiate cell division. Protein kinases, which can be activated by cyclins (a class of regulatory proteins whose concentrations fluctuate cyclically during the cell cycle), regulate other proteins by phosphorylation; they also control the sequential steps of the cell cycle. In short, after the cell passes the checkpoint and is committed to reproduction, cell division is carried out as instructed by regulatory proteins (e.g., kinases, cyclins) in a cyclical manner.

2.3 MEIOSIS

Another form of cell division is meiosis, which occurs only in the ovaries and testes. Meiosis produces the reproductive cells, or gametes (i.e., ova and sperm cells), and reduces the chromosome number by half. Among the 46 human chromosomes, there are two of each type having the same length, centromere position, and band pattern. Such chromosomes are paired up and are referred to as homologous chromosomes, carrying genes controlling the same inherited traits. Each homologous chromosome in each pair is inherited from each parent. The 46 chromosomes can be organized into two sets of 23 chromosomes, with one set from the mother and the other set from the farther.

There are two distinct human sex chromosomes: X and Y. Females have a homologous pair of X chromosomes, while males have one X and one Y. X and Y are called sex chromosomes, and the others (i.e., 22 pairs) are called autosomes. Each gamete with a single set of 23 chromosome is a haploid cell. Fertilization of the gametes (a haploid sperm cell fuses with a haploid ovum, resulting in a fertilized egg known as a zygote) brings the chromosomal number back to 46. Somatic cells are derived from the zygote by mitosis during the development of a sexually mature adult. Diploid cells include the zygote and the somatic cells that have two sets of chromosomes.

Fertilization and meiosis are two features of sexual reproduction and are common to all organisms that reproduce sexually, although the details of sexual life cycles vary across species. The stages of meiotic cell division, using an animal cell as an example, are further illustrated next.

Interphase, during which each of the chromosomes replicates, is similar to mitosis. After chromosome replication, four daughter cells with only half as many chromosomes as the parent are formed through two meiotic divisions, meiosis I and meiosis II. During meiotic prophase I, two side-by-side homologous chromosomes pair up with each other in a process called synapsis. Chromatids of homologous chromosomes are criss-crossed in a process known as chiasma (see Figure 2.3). From one side this structure helps hold homologous chromosomes together; from the other side, it may result in significant genetic variations in the offspring (discussed in a later section). The two centrosomes move away from each other, and early spindle microtubules are formed between them that are similar to those observed during mitosis.

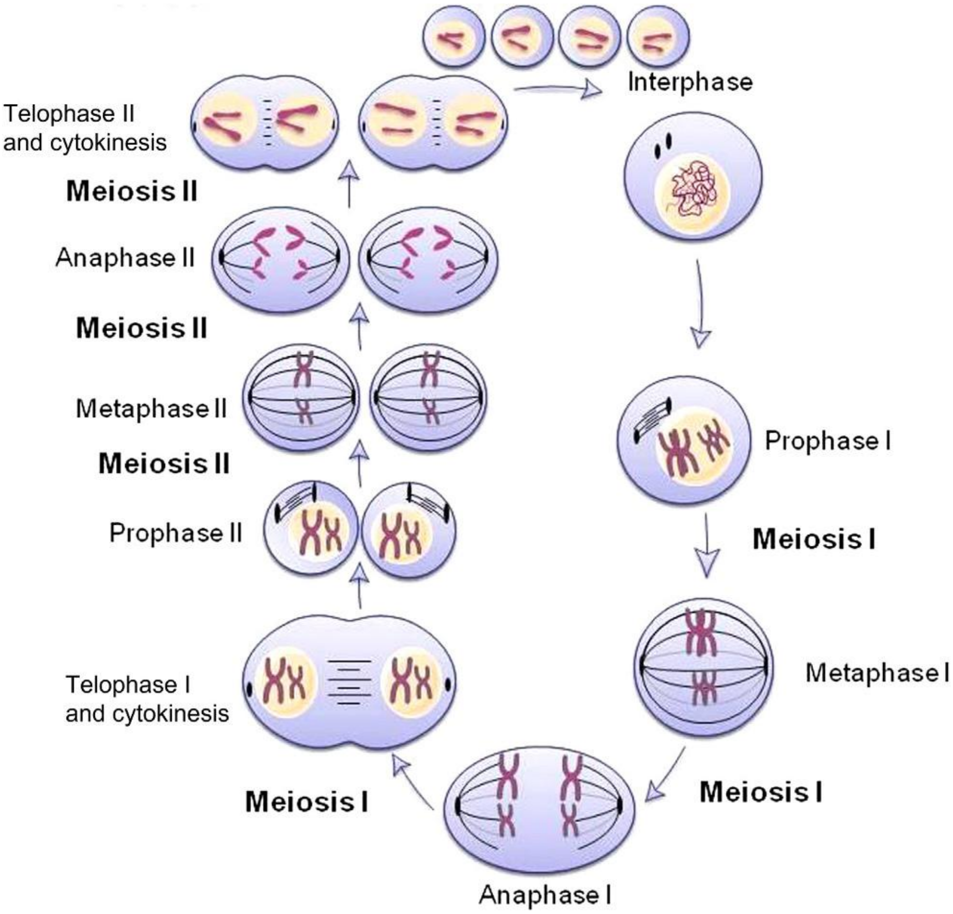

FIGURE 2.3 **Cell division—meiosis in an animal cell with a diploid number of 4 (or two sets of chromosomes).**

During metaphase I, the paired homologous chromosomes are arranged on the spindle equator. Spindle fibers from opposite poles attach to one chromosome of each pair, respectively. During anaphase I, homologous chromosomes move toward the two spindle poles; however, sister chromatids of each chromosome remain attached at the centromere and move together toward the same pole. During telophase I, the homologous chromosome pairs continue to be separated by the spindle. The homologues are finally split, and each pole now has a haploid chromosome set. Cytokinesis occurs at the same time and leads to the formation of two daughter cells at the end of meiosis I.

There is no further chromosomal replication prior to meiosis II, which also includes four subphases like the ones in meiosis I—prophase II, metaphase II, anaphase II, telophase II, and cytokinesis (see Figure 2.3). The differences are that, during metaphase II, chromosomes align in a similar manner to that observed in mitosis, with the spindle fibers attaching to the kinetochores of each chromosome's sister chromatids; during anaphase II, these sister chromatids move toward opposite spindle poles. Four daughter cells are formed following telophase II and cytokinesis, and each daughter cell has a haploid number of chromosomes compared to the zygote or the somatic cells. Table 2.3 compares mitosis and meiosis in an animal cell.

2.3.1 Genetic Variation Introduced by Meiosis: The Mechanisms

At the chromosomal level, a crossing over of two nonsister chromatids of homologous chromosomes during meiosis I (i.e., prophase I) results in individual chromosomes inheriting a portion of DNA from both mother and father. Such an exchange, or crossover, accounts for the recombination of linked genes on the same chromosomes. Independent assortment of chromosomes and random fertilization are also sources of genetic variability.

During meiosis I (i.e., metaphase I), a pair of homologous chromosomes orient independently of any other pair in terms of orientation relative to the two poles of the cell. Starting with two pairs of homologous chromosomes, there are four different combinations possible for a gamete. Based on the haploid number (n), the total number of combinations for the gametes generated by meiosis can be

TABLE 2.3 Comparison of Mitosis and Meiosis in an Animal Cell

	Mitosis	Meiosis
DNA replication	Occurs during interphase	Occurs during interphase
Division number	One division, including prophase, metaphase, anaphase, and telophase	Two divisions (meiosis I and II), each consisting of prophase, metaphase, anaphase, and telophase; homologous chromosomes joining along their length are unique to meiosis
Division outcome	Results in two daughter cells (diploid) genetically identical to the mother cell	Results in four daughter cells (haploid); genetically nonidentical to the parent cell
Significance	Derived from the zygote and has a positive effect on cell growth for repairing tissues	Gamete production; compensates chromosomes' doubling during fertilization by reducing the number of chromosomes to half; produces genetic variability in gametes

calculated as 2^n. In the case of humans, the haploid number is 23; thus, the number of all possible combinations in the gametes is 2^{23}. This independent assortment of homologous chromosomes produces about 8 million chromosomal combinations for human gametes. It produces another form of genetic recombination among unlinked genes that locate on separate nonhomologous chromosomes.

Random fertilization adds another layer to the creation of genetic variations. For a zygote to form, a human ovum representing one out of 8 million possible chromosome combinations is fertilized by a sperm cell, whose chromosome composition presents 8 million different possibilities as well. Therefore, without taking crossover into account, 64 (8×8) million diploid combinations for a zygote are possible.

The three mechanisms just described reorder the genes carried by individuals in a population; nevertheless, the fundamental factor that explains genetic diversity in a population is mutation.

2.4 MENDELIAN LAWS

Around 1857, Gregor Mendel began breeding garden peas in an abbey garden to study the mechanism of inheritance. In this section, we examine in detail the heredity principles developed by Mendel and the application of his model to the inheritance of human variations.

Mendel's choice of the pea as his experimental organism may be explained as follows. First, there are many varieties of peas. For example, flower color, seed color, and shape vary among different pea varieties, and such characteristics can all be used to observe inheritance patterns. Second, working with peas allowed Mendel to strictly control hybridization. Since carpels and stamens are almost completely enclosed by the petals of pea flowers, instead of allowing self-fertilization from the same plant, Mendel could cross-pollinate between different varieties (e.g., pea plants with different flower color) by removing the immature stamens and transferring pollen from another plant onto the emasculated flowers. In this way he controlled the parentage of the hybridized seeds.

In his breeding experiments, Mendel cross-pollinated purple-flower and white-flower pea plants and ensured that both plant types (either purple flowers or white flowers) were self-pollinated in the first place and that their offspring were of the same variety. This is known as true breeding (e.g., a purple-flower plant always produces offspring having purple flowers through self-pollination). Hybridization is defined as the mating of two true-breeding varieties. The true-breeding parents are referred to as the P generation, and the first generation of offspring is referred to as the F_1 generation. Self-pollination of the F_1 generation produces the F_2 generation. Mendel followed these generations in his experiments. It was after the quantitative analysis of the F_2 generation that two main principles of heredity were revealed: the law of segregation and the law of independent assortment.

2.4.1 The Law of Segregation

In his flower color breeding experiments, Mendel used the true-breeding peas, with purple and white flowers respectively, as the parental (or P) generation. Like their parents, the F_1 offspring all had purple flowers. Mendel allowed them to self-pollinate, and the white-flower peas reappeared in the F_2 generation. More specifically, Mendel observed 705 plants with purple flowers and 224 with white flowers. An approximate ratio for this observation is 3 (purple) to 1 (white). Along with flower color, Mendel examined the pattern of inheritance for flower position, seed color, seed

shape, pod shape, pod color, and stem length; he observed that all of the pea plants followed the same pattern of inheritance as that seen in flower color, with a typical ratio of 3:1 in the F_2 generation.

Mendel developed a theory to explain the observed inheritance pattern in flower color that can be separated into four hypotheses:

- Different versions of genes account for variations appearing in the F_2 generation. For example, an alternative gene version is present in white flowers relative to the version in purple flowers. Different gene versions are now known as alleles.
- Two alleles from each parent are inherited to represent a trait. This is not difficult to understand given what we encountered during the discussion of meiosis: in a diploid cell, one homologous chromosome of a pair is inherited from each parent; a genetic locus is thus represented twice along the paired homologous chromosomes. The alleles may be matched at a homologous locus—for example, the true-breeding P generation in flower color—and the alleles may be different at the same locus—for example, the F_1 generation (see Figure 2.4).
- Two different alleles can be either dominant (fully expressed to control for an organism's appearance) or recessive (no noticeable effect on appearance). Thus Mendel's F_1 plants inherited a purple-flower allele from one parent and a white-flower allele from the other parent. That the F_1 plants are purple is possibly because the purple-flower allele (the *P* allele, as shown in Figure 2.4) has a dominant effect on flower color, while the white-flower allele (the *p* allele, as also shown in Figure 2.4) is a recessive allele and its effect on flower color is masked by the dominant *P* allele.
- The two alleles segregate during the formation of a gamete, which means that the reproductive cell (sperm or ovum) has only one of them. As in the F_1 plants, half of the gametes receive the dominant allele and half receive the recessive allele (Figure 2.4). The separation of alleles into gametes is actually the central idea of Mendel's law of segregation.

Figure 2.4 shows how the model of segregation explains the 3:1 ratio observed in the F_2 generation. Two classes of F_1 gametes are formed. When alleles segregate, half of the gametes receive a *P* allele (purple flower) and the rest receive a *p* allele (white flower). During self-pollination, the two classes of an ovum's gametes unite randomly with the two classes of a sperm's gametes, resulting in a total of four possible combinations in a fertilized egg. In the F_2 generation, one-fourth of the plants apparently have two *P* alleles, leading to the expression of purple flowers. Half of the plants have one *P* and one *p* allele and have purple flowers according to the third hypothesis. One-fourth of the F_2 offspring have white flowers with the two *p* alleles, expressing the recessive white flower feature. This accounts for the exact ratio of 3:1 observed in the F_2 generation.

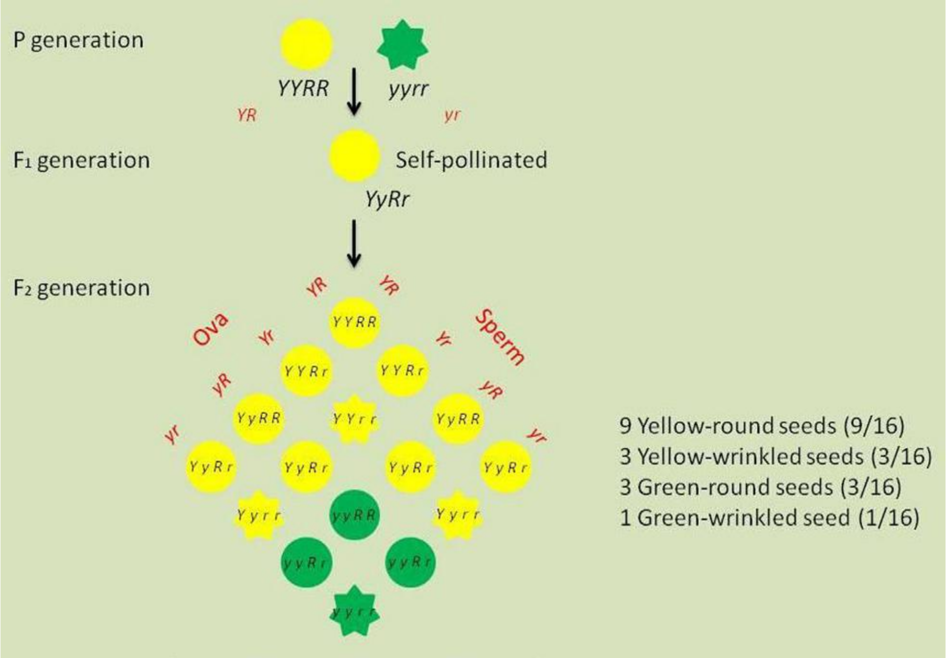

FIGURE 2.5 **Mendel's law of independent assortment.** Shown is Mendel's crossing experiment between true-breeding parents differing in two characters, seed color and seed shape.

A pair of identical alleles of a gene accounting for an inherited trait is said to be homozygous for that gene. Two different alleles at the same genetic locus representing a trait are said to be heterozygous at that locus. In the example of flower color in peas, *PP* and *pp* are homozygous for purple and white flowers, respectively, with *Pp* as the heterozygous type. Another concept that describes the observed physical appearance is the phenotype, whose genetic makeup is called its genotype. In the same case of flower color, both *PP* and *Pp* express the dominate phenotype of purple flowers, but they are different genotypes.

2.4.2 The Law of Independent Assortment

Mendel discovered the model of allele segregation into gametes using parental varieties that differ in a single character (e.g., flower color). He also conducted mating experiments on parental varieties differing in two characters (e.g., seed color and shape). From previous crossing experiments in single characters, including seed color and shape, Mendel already knew that yellow is a dominant trait (for the *Y* allele) relative to green (for the *y* allele), and that round is a dominant trait (for the *R* allele) relative to wrinkled (for the *r* allele). Breeding a plant with yellow-round seeds (*YYRR*) to a plant with green-wrinkled seeds (*yyrr*), produces F_1 offspring with yellow-round seeds (*YyRr*). Following self-fertilization of the F_1 plants, will the *Y* and *R* alleles still be transmitted together to the F_2 generation, or will the two allele pairs segregate independently of each other? To answer this question, we now take a look at the overall design and theoretical outcome of Mendel's experiment on crossing peas differing in both seed color and shape (Figure 2.5).

The experiment produces a ratio of 9:3:3:1 in the F_2 generation: nine yellow-round seeds, three yellow-wrinkled seeds, three green-round seeds, and one green-wrinkled seed (Figure 2.5). In this example, four gametes are formed given self-pollination of the F_1 generation: *YR*, *Yr*, *yR*, and *yr*. When these four ovum classes are fused with four sperm classes, 16 different combinations of gametes' alleles are generated in the F_2 offspring (Figure 2.5). The results of this experiment support the independent segregation of each pair of alleles into gametes. Indeed, Mendel obtained 315 yellow-round, 108 green-round, 101 yellow-wrinkled, and 32 green-wrinkled seeds from his experiment—a ratio of roughly 9:3:3:1. This pattern of inheritance is now defined as Mendel's law of independent assortment.

2.4.3 Mendelian Patterns of Inheritance in Humans

In modern genetics, Mendelian principles have been extended to more complex inherited traits than Mendel described. His peas have a relatively simple genetic basis—each character is determined by only one gene with two versions (or alleles), of which one is completely dominant. In fact, the relationship between genotype and phenotype for the majority of heritable traits is very complicated, but the laws of segregation and independent assortment can still be applied.

Recall from previous sections that pea characters, such as flower color, seed color, and seed shape, are completely controlled by their respective dominant alleles: *P*, *Y*, and *R*. In the case of flower color, Mendel's heterozygous F_1 offspring (*Pp*) all had purple flowers because the *P* allele shows a completely dominant effect over the recessive *p* allele. However, some heterozygous genotypes may cause incomplete dominance, meaning that the appearance of those heterozygous individuals has an intermediate phenotype between the phenotypes of the parent generation. Along with complete and incomplete dominance patterns of inheritance, there is co-dominance, in which a heterozygous individual expresses both phenotypes of the two alleles. Furthermore, the dominant effect of one allele on a phenotype is reflected by the mechanisms/pathways from genotype to phenotype, which does not imply the ability of one allele to mute another at the DNA level or the abundance of that allele in a population.

The relationship between genotype and phenotype may also be explained by multiple gene alleles (instead of only the two reported by Mendel); pleiotropy (i.e., one gene affects several phenotypic traits); epistasis (i.e., a gene at one locus interferes with the expression of a second gene at a different locus); and environment (e.g., nutrition affects human height and sun exposure affects skin color). Some characters, such as human height and skin color, result from an additive effect of two or more genes in a continuous fashion. These characters are said to be polygenic. Environment influences these polygenic traits, which are thus known as multifactorial.

Mendel's discovery of the patterns of individual gene transmission from parents to offspring led to Mendelian models, which were developed and broadly used to explain the inheritance patterns of epistasis and polygenic characters. In the case of human inheritance, family pedigree analysis shows evidence that supports Mendelian patterns, with some following those patterns recessively (i.e., inherited from the heterozygous genotype) or dominantly (i.e., inherited from the dominant allele). Besides these simple Mendelian disorders, humans are more prone to diseases that have a multifactorial basis. For example, heart disease, diabetes, cancer, and many others diseases are the result of multiple genes, interactions between genes, and interactions between genes and the environment. Using technologies developed in recent years, studies have been conducted on the genetic and environmental components of multifactorial human traits. These will be discussed in later chapters.

2.5 PUBLIC DATABASES FOR BIOMEDICAL RESEARCH IN HUMANS

Groups of researchers have formed large-scale, international collaborations with the goal of creating accessible public databases of human genetic or epigenomic data. These databases will aid basic biomedical research that promotes understanding of the biology of human health and disease. Such projects include the International HapMap Project, the 1000 Genomes Project, the Encyclopedia of DNA Elements (ENCODE), and the Roadmap Epigenomics Project.

The International HapMap Project (http://hapmap.ncbi.nlm.nih.gov/) focuses on the identification of the common patterns (haplotypes) of genetic variations and the determination of tag single-nucleotide polymorphisms (SNPs) that represent them. Analysis of 1.6 million SNPs in 11 populations of African, European, and Asian ancestries has been carried out, with a total sample size of 1184 (HapMap Phase I, II, and III, called "HapMap 3") [1]. This integrated dataset effectively captures common variants with minor allele frequency (MAF) of $\geq 5\%$ in the related populations, and it has improved imputation accuracy for variants with lower frequencies ($\text{MAF} \leq 5\%$). The project provides a robust reference panel for studying human genetic variation across various diseases and other common complex traits [1].

In October 2012, the 1000 Genomes Project (www.1000genomes.org/) Consortium announced the sequencing data from 1092 human genomes for 14 populations drawn from Europe, East Asia, Sub-Saharan Africa, and the Americas. This includes low-coverage whole-genome sequence data (2–6 times), targeted deep-exome sequence data (50 times), and dense SNP genotype data. Ultimately, ~2500 individuals from 26 populations will be sequenced. The aim of the 1000 Genomes Project is to generate a more comprehensive catalog of genetic variations by capturing SNPs at a frequency of 1% in the human genome [2].

ENCODE (http://genome.ucsc.edu/ENCODE/), funded by the National Human Genome Research Institute (NHGRI), began in September 2003 with the aim of identifying all functional elements in the human genome. These include protein-coding regions, RNA-transcribed regions, transcription factor binding sites, chromatin structure and histone modification sites, and DNA methylation sites. So far, the overall results reflect only a small portion of the potential functional elements encoded in the genome [3]. Other factors, modifications, and cell types can be studied and added to create a larger and more comprehensive database for understanding the functions of the human genome. Also, integration with other, related projects (for example, the Roadmap Epigenomics Project) will allow a deeper analysis of genes and regulatory factors and an understanding of the mechanisms of regulation [3].

The Roadmap Epigenomics Project (www.roadmapepigenomics.org/) was developed for documenting human epigenomic data to map DNA methylation, histone modification, chromatin accessibility, and small RNA transcripts using next-generation sequencing technologies in stem cells and *ex vivo* normal tissues. These are representative of the tissues involved in human disease. Normal epigenomes are provided and serve as a reference for possible combined investigation with other projects. The raw sequence data, epigenomic signatures, and integrated maps are released rapidly into the public domain. Standardized protocols and analytical tools are also provided as guidelines to the scientific community.

2.6 CONCLUSION

In this chapter, we first looked at the cell structure and function of organelles using an animal cell. We then moved to the topics of cell division, including mitosis, which produces two daughter cells identical to the parent cell, and meiosis, which generates four daughter cells different from the parent cell as well as from each other. Last, we reviewed Mendel's crossing experiments on garden peas and the fundamental concepts of inheritance revealed by his experiments. The impact of these principles on human genetics was also reviewed, followed by information on several publicly available databases for human biomedical research.

GLOSSARY

Allele one version of a gene at a given locus along a chromosome

Band During cell division, the specific staining pattern (light and dark stripes) is observed for chromosomes. Such patterns can help in identifying chromosomes and evaluating their structure

Binary fission a type of cell division that applies to prokaryotes, such as bacteria. One cell is divided in two, with two complete and identical genomes present in the two daughter cells

Centromere a constricted chromosomal region that holds sister chromatids together during cell division. The centromere also separates a chromosome into a short arm and a long arm

Character a heritable feature that varies among individuals

Chromatid during the S phase of the cell cycle, each chromosome is duplicated. Following replication, each chromosome consists of two identical sister chromatids, which contain matched copies of the DNA sequence at every locus

Chromatin fiber the 30 nm coil of DNA and proteins that forms the basic structure of chromatin

Cytokinesis the division of the cytoplasm. Cytokinesis immediately follows the division of the nucleus

Cytoskeleton protein filaments within cells that maintain cell shape and cell movement

DNA the molecule that encodes the genes responsible for the structure and function of an organism. Genetic information carried by DNA molecules is transmitted from one generation to the next

DNA methylation methyl groups, consisting of one carbon atom and three hydrogen atoms, attach to DNA molecules at cytosine bases, resulting in reduced transcription of the gene

Endomembrane system all membranes, which are suspended in the cytoplasm within a cell, can divide the cell into structural and functional compartments/organelles. In a eukaryotic cell, endomembrane organelles include the nuclear envelope, the endoplasmic reticulum, the Golgi apparatus, lysosomes, vacuoles, vesicles, and the cell membrane. The endomembrane system does not contain mitochondrial membranes

Epigenomics the study of global gene expression changes caused by epigenetic processes that do not involve any change in the underlying DNA sequence

Epistasis the expression of one gene depends on the expression of one or more independently inherited genes

Eukaryote an organism whose cells contain a nucleus and other membrane-bound components. Many unicellular organisms, such as protozoa, are eukaryotes. All multicellular organisms—animals, plants, and fungi—are eukaryotes

Exome the part of the genome that corresponds to exons, which are the coding sequences of DNA present in mature messenger RNA. The exome constitutes about 1% of the total human genome

Gamete a cell/gamete that carries half the genetic information of an individual fuses with another cell/gamete in organisms that reproduce sexually. There are two types of gametes: a sperm is produced by a male and an ovum is produced by a female

Gene the basic physical unit of heredity. For example, a segment of DNA that is arranged in a linear manner along a chromosome is a gene. A gene codes for a specific protein that has a particular characteristic or function

Genome the entire genetic material found in a cell. In the case of humans, the genome includes 23 pairs of chromosomes in the nucleus and the chromosomes contained in a cell's mitochondria

Genotype the genetic make-up of a cell or organism. Also, a set of alleles inherited at a locus

Haplotype a set of alleles or single-nucleotide polymorphisms found on the same chromosome, tending to be inherited together

Imputation in statistics, imputation is a process of replacing missing data with other estimated probable values. In genetics, imputation is a method used to fill in missing genotypes in a study dataset

Kinetochore a protein structure on chromatids, allowing the spindle fibers to attach and pull the sister chromatids apart during cell division

Linked genes genes on the same chromosome tend to be segregated and inherited together

Locus the location or the physical site of an individual gene or DNA sequence on a chromosome

Minor allele frequency the frequency of the least common allele in a given population

Mutation an alteration in a DNA sequence from its natural state. The effect of any mutation might be deleterious or benign

Next-generation sequencing a high-throughput sequencing technology relative to capillary electrophoresis–based Sanger sequencing, producing thousands or millions of sequences simultaneously. This technology can be applied to DNA analysis, RNA analysis, and gene regulation analysis

Organelle a subcellular structure within a cell. An organelle is usually enclosed by its own membrane for executing its specific function independently of other organelles in a cell, particularly a eukaryotic cell

Organism any living system that has the ability to grow, reproduce, maintain homeostasis within itself, and function independently. An organism may be either unicellular or multicellular. All organisms on Earth can be further divided into eukaryotes and prokaryotes

Phenotype a gene's expression of observable physical and/or biochemical characteristics. Some phenotypes are heavily influenced not only by genes but also by the environment

Pleiotropy multiple physical effects caused by a single gene. The underlying mechanism of pleiotropy may be a gene involved in different metabolic pathways that contribute to different phenotypes

Prokaryote an organism lacking a membrane-enclosed nucleus. Most prokaryotes are unicellular. No membrane-bound organelles are present in the prokaryotic cells. The intracellular components of a prokaryotic cell are gathered together and enclosed only by the cell membrane

Recombination the new combinations of the traits in offspring that are inherited from its parents, now more commonly known as the exchange of a DNA segment between two homologous chromosomes during meiosis, which causes new combinations of hereditary material in a gamete

RNA a molecule synthesized from the DNA template, with the alternating sugar ribose to replace the deoxyribose present in a DNA molecule. Different types of RNA exist in a cell: messenger RNA, ribosomal RNA, transfer RNA, and some small RNAs

Sequencing the technique for determining the exact DNA sequence or nucleotides (A, C, G, and T). DNA-sequencing technology is developing fast and becoming less expensive. For example, whole-genome and whole-exome sequencing is now available for studying the association between a DNA sequence and a disease

Single nucleotide polymorphism a change in a single nucleotide at a genetic locus with a minor allele frequency of 1% or higher in a population

Somatic cell the cell forms the body of an organism. For example, in humans, somatic cells form all internal organs, skin, bones, and connective tissues. Somatic cells are diploid

Synapsis the pairing of two homologous chromosomes at the early stage of meiosis. This allows the matching of homologous chromosomal pairs and prepares for possible crossover between them

Trait a variant of a character, which may be determined by genes, the environment, and the interactions between the two

3.1 OVERVIEW: STRUCTURE OF THE HUMAN GENOME

The size of the human genome in the chromosomes of the nucleus is approximately 3100 million (3.1×10^9) base pairs (bp). This is the total length of the DNA in a haploid (i.e., half) set of human chromosomes, and it is based on the GRCh37-computed genome assembly (as updated in June 2013). Only around 1–1.5% of the human nuclear genome constitutes coding DNA or protein-encoding genes. This is consistent with the fact that there are approximately 23,411 protein-encoding genes (including alternative sequences, based on the GRCh37 dataset) and that the size of the coding region of a nuclear human gene is usually 1–3.5 kbp.

At the time of writing, there are also reported to be 9719 short noncoding genes and 14,335 long noncoding genes (although the Ensembl Genome Browser should be checked for updated figures; see [1,2]). Approximately 20% of the genome consists of introns and untranslated regions of genes, as well as other sequences that are related to genes, such as pseudogenes. Most of the remainder of the genome, constituting 75% of its total size, is extragenic, however, and as much as around 55% of the genome comprises repeated sequences. This repetitive sequence is predominantly composed of transposons (transposable elements) that can insert multiple copies of themselves in the genome in scattered locations. Interestingly, the proportion of the human genome that consists of repetitive sequences (i.e., 55%) is rather higher than in other organisms, such as the worm and the fly, in which the corresponding proportions are 7% and 3%, respectively. However, through rearrangement of regions of the genome by recombination, these repetitive sequences have permitted the structural modification of existing genes and even the creation of new ones.

Nucleic acid is the carrier of genetic information, and it is of two principal types: DNA (deoxyribonucleic acid) and RNA (ribonucleic acid). Both consist of a sugar–phosphate

Handbook of Pharmacogenomics and Stratified Medicine. http://dx.doi.org/10.1016/B978-0-12-386882-4.00003-7
© 2014 Elsevier Inc. All rights reserved.

backbone together with projecting nitrogenous bases. In DNA, the sugar is deoxyribose, whereas in RNA it is ribose. The bases are attached to the 1′ (one prime) position of each sugar, and the backbone is formed by the linking of 3′ and 5′ hydroxyl groups by a phosphate. A nucleotide is the unit consisting of a purine or pyrimidine base together with the attached sugar and phosphate group(s). In DNA, there are two pyrimidine bases, thymine (T) and cytosine (C), and two purine bases, adenine (A) and guanine (G). RNA also contains the bases cytosine, adenine, and guanine, but it contains uracil (U) instead of thymine (see [3]).

A molecule of DNA is composed of two strands, or chains, of nucleotides, which are coiled clockwise around each another. They form a double helix, with the two chains running in opposite directions (i.e., 5′ to 3′ for one and 3′ to 5′ for the other). There are 10–10.5 nucleotides per complete turn. The strands are held together by hydrogen bonds between the bases—i.e., between A in one chain and T in the other or between G and C. This base pairing is very specific, and, because A:T and G:C pairing is obligatory, the parallel strands must be complementary to one another. Thus, if one strand reads 5′-ATGC-3′, the complementary strand must read 5′-GCAT-3′ (not 5′-TACG-3′). Wide variation exists in the (A + T): (G + C) ratio, with higher plants and animals tending to have an excess of A + T. In humans, for instance, the ratio is 1.4:1.

DNA's unit of length is the base pair (bp), with 1000 bp in a kilobase (kb) and 1,000,000 bp in a megabase (Mb). Its total length in a half (haploid) set of human chromosomes is approximately 3100 Mb (3.1×10^9 bp), as mentioned previously, and as the distance between base pairs in the DNA helix is 0.34 nm, the total length of haploid DNA if extended per cell is 1 m.

Each protein-coding gene is usually present as just one copy in the haploid genome. Well-known exceptions, however, are α-globin, histone, and ubiquitin genes. The average size of a gene is 53.6 kb with an average intergenic distance of 60–70 kb. The majority of the genome is noncoding and repetitive and has no proven function. Work conducted in 2012 by the ENCODE Project Consortium suggests that many noncoding regions may have biological activities, at least in one or more cell lines used in experiments. Repetitive DNA is subdivided into tandem (multiple adjacent) repeats (satellite DNA) and interspersed (single) repeats.

Tandem repeats are subdivided according to their length. Microsatellite repeat arrays are under 1 kb in length, and the most common repeat motifs are A, CA, AAAN (where N is any nucleotide), AAN, and AG. The arrays of CA motifs commonly have 10–60 repeats and are found approximately every 36 kb. The repeat number on corresponding chromosomes typically differs, and these common genetic differences, or polymorphisms, have often been used to track the inheritance of that region of each chromosome. Single-nucleotide polymorphisms (SNPs) can now be used for this purpose.

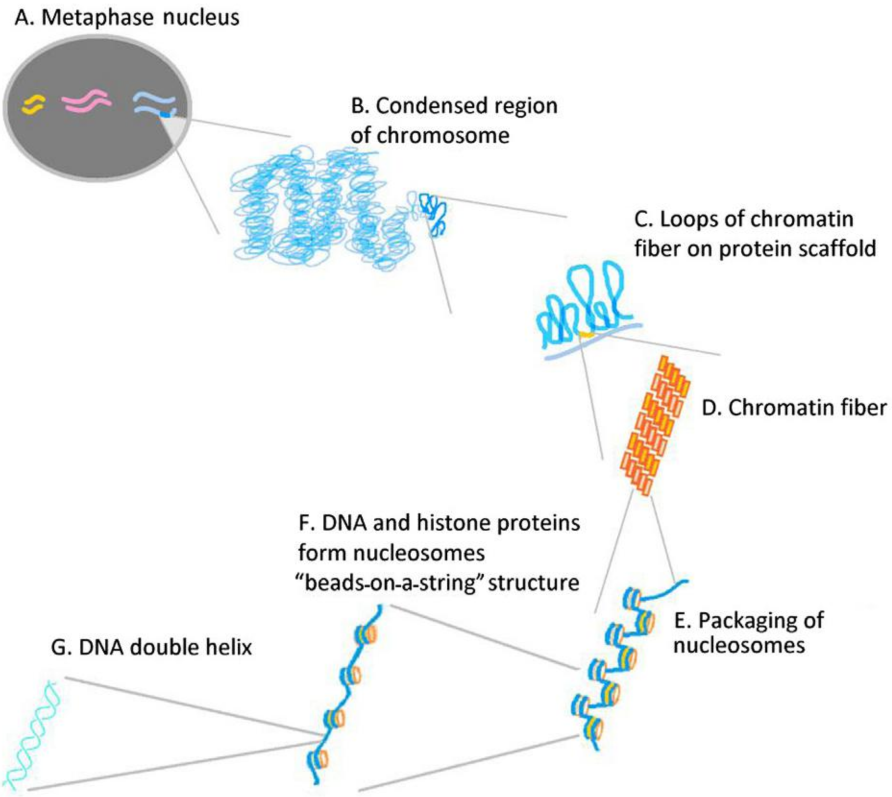
Minisatellite repeat arrays are usually 1–30 kb in length and have longer repeat motifs than do microsatellite repeats, but again they show marked variation in repeat number. Macrosatellite repeats are even longer and may be many megabases in length. They are found at the ends (telomeres) of the chromosomal arms and in the central chromosomal constriction (the centromere). Length variation is common and, in fact, accounts for visible differences in the size of chromosomal centromeric regions.

In contrast, interspersed repeats usually occur as single copies and are subdivided according to their length. Short interspersed repeats (SINES) are less than 500 bp in length, and the commonest of these is the Alu. SINE length is approximately 300 bp, and SINES contain a cutting site for the restriction enzyme *Alu*. Alu repeats are very common (constituting 11% of all DNA), occurring every 5–10 kb. Long interspersed repeats (LINES) vary from 500 bp to 10 kb (most often 6–8 kb) in length and include three families that in total constitute about 20% of the human genome. The most common is the LINE-1 (L1) element, which, like other LINES, possesses structural similarities to retroviruses. It can replicate itself and insert a copy elsewhere in the genome. This retrotransposition may disrupt a gene at the new location and cause a genetic disorder (e.g., hemophilia).

Single-copy and repeat DNA is double-stranded, whereas RNA is single-stranded and subdivided into several types. Transfer RNAs (tRNAs) are synthesized directly on a DNA template and, although 61 types might be expected, surprisingly only 49 are found because some tRNAs can bind to more than one mRNA codon. This results from relaxed base pairing ("wobble") at the third-base position of the codons. The DNA templates for tRNAs tend to occur as multiple copies, which may be clustered or dispersed. Ribosomal RNAs (rRNAs) are also synthesized directly on DNA templates, which again occur as multiple clustered copies. These are located in the nucleolus organizer regions on the short arms of chromosomes 13–15, 21, and 22, and also on chromosome 1. The ribosomal RNAs are synthesized as large precursors in the nucleolus and then enzymatically cleaved.

3.1.1 Chromatin Structure

DNA and proteins are assembled and folded into structures that allow for compaction of the entire genome into the microscopic cell nucleus. This arrangement of DNA wound around proteins and into further higher-order structures is known as chromatin. At the most basic level, classically known as the "beads on a string" structure, 146



A. Metaphase nucleus
B. Condensed region of chromosome
C. Loops of chromatin fiber on protein scaffold
D. Chromatin fiber
F. DNA and histone proteins form nucleosomes "beads-on-a-string" structure
E. Packaging of nucleosomes
G. DNA double helix

FIGURE 3.1 **Organization of DNA within the nucleus.** Chromosomes are condensed in the metaphase nucleus and align along the metaphase plate in preparation for cell division. Looping fibers of chromatin on a protein scaffold are further folded into these condensed regions; they are made up of packaged nucleosome structures. Nucleosomes consist of 146 bp of DNA double-helix and histone proteins, appearing as "beads on a string" when viewed by electron microscopy. *Source:* [4].

base pairs of DNA are wound about 1.65 times around an octamer of histone proteins, constituting the nucleosome [5]. As illustrated in Figure 3.1, the organization of different levels of DNA into higher-order structures to achieve very high levels of compaction is complex (see [4,6]).

Chromatin structure is extremely dynamic and varies between loci on chromosomes and between tissue and cell types. To understand the manner and mechanism of this structural variation, first we must understand the different chromatin states that have been observed. Chromatin in loose or relaxed structures associated with active genes is commonly known as *euchromatin*, whereas tight or closed structures that tend to correspond to silent regions of the genome are referred to as *heterochromatin*. Heterochromatin can be subdivided into two categories: *constitutive* and *facultative* (see [4]). The first type is always found in a closed conformation and is therefore silent and not reversible; it will always exist in this closed state in an organism. Facultative heterochromatin, however, can be reversed to euchromatin and the genes in this region can therefore be expressed, often in response to signaling or external stimuli in processes such as development. Open regions are thought to be more actively expressed because of the ability of the transcription complexes and machinery to access the DNA and thus transcribe the genes in such a region. By this same reasoning, the genes in closed structures cannot be transcribed, as the interactions required between the DNA and other transcriptional components are not physically possible.

It is by these mechanisms that tissue-specific expression of particular regions of the genome is carried out. Regulation and control of the orchestration of such complex nuclear organization is mediated through chemical modifications of the histone tails in the nucleosome structure; these histone tails induce associations with further proteins in the cell and modify chromatin structure.

3.1.2 The Nucleosome

As previously mentioned, the nucleosome consists of DNA and an octamer of histone proteins; it is the basic component of chromatin structure. The histone proteins and their

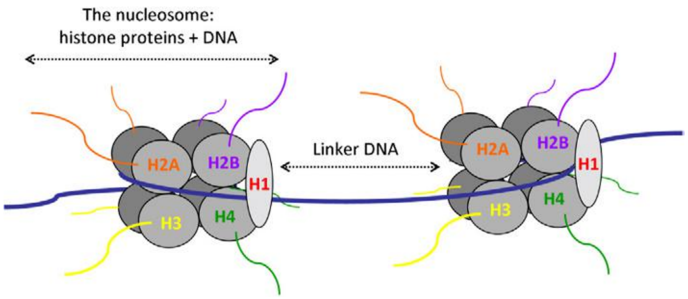


FIGURE 3.2 **The structure of the nucleosome.** The N-terminal tails of the histone proteins are not contained in the core of the DNA-histone complex; they project outward and thus can be easily accessed and modified by enzymes to ultimately alter overall chromatin structure in one particular genome region. Such modifications vary between regions in different cells and tissues. *Source:* [6].

modifications facilitate the opening and closing of chromatin structures, permitting or preventing gene transcription (see [6]). As seen in Figure 3.2, the N-terminal tails of the histone proteins protrude out of the nucleosome structure, allowing these residues to be subject to post-translational chemical modifications. Combinations of the modifications to specific residues on these tails, known as the "histone code," influence the DNA and chromatin interactions that can take place.

3.2 GENE STRUCTURES

Gene size is highly variable, ranging from small genes such as the globins to enormous genes such as titin and dystrophin (the largest, at over 2 million base pairs in length). A typical protein might contain about 300 amino acids, which are encoded by 900 bp of DNA. The vast majority of genes consist of protein-encoding exons alternating with noncoding segments, called intervening sequences or introns. The function of introns is still largely unknown, and they range from 50 bp to more than 10,000 bp in length. As a result of the presence of additional sequences, including these intervening sequences and also 5′ and 3′ flanking sequences, human genes are generally much larger than would be calculated from the encoded protein's amino acid sequence alone.

The initial mRNA (heterogeneous RNA or hnRNA) is a transcript of the gene that includes not only the exons but also the intervening sequences and some flanking sequences. The introns are removed from the hnRNA before it enters the cytoplasm by the process known as splicing. This requires the action of splicing proteins, which recognize particular sequences that are fairly well conserved at sites around the intron/exon junctions. Thus the sequence of an intron commences with GT (the 5′ splice donor site) and ends with AG (the 3′ splice acceptor site). Mutations in the bases adjacent to the exon/intron boundaries interfere with mRNA splicing and can lead to genetic disease by, for example, causing retention of an intron in the mature mRNA or abnormal removal of an exon. (see [3])

Each end of the mRNA is modified. At the 3′ end, the 3′ untranslated region (3′ UTR) extends from the protein translation stop codon to a poly(A) tail. This tail of 100–200 adenylate residues is not encoded in the DNA but is added enzymatically to aid cytoplasmic transport and, possibly, mRNA stability. At the 5′, a different modification is made: the end is protected or "capped," with a methyl guanylate residue, and the 5′ UTR extends downstream from this cap site to the beginning of the protein-encoding sequence.

Following ribosomal translation, many proteins are still not in their final form. Subsequent post-translational alterations include the formation of disulphide bonds (which can be structurally important for the protein), glycosylation, and proteolytic cleavage. Each step in the production of the final protein is important, as many proteins are highly dependent for functioning on their exact three-dimensional shape (or "tertiary structure"). This in turn is determined by the amino acid sequence and post-translational modifications of the protein. In general, acidic and basic amino acids are found on the surface of a folded protein, with hydrophobic amino acids being internally oriented. The effect of an amino acid substitution (and the degree of consequent disruption to the protein's tertiary structure) thus depends upon the amino acid's location relative to the active site of the protein. It can also depend, however, on the change in amino acid charge or the amino acid's affinity for water molecules.

3.2.1 Number of Genes

Chromosomes contain markedly different numbers of genes. For instance, the largest chromosome, chromosome 1, contains 2079 (the most protein-encoding genes), the X chromosome contains 830, and the Y chromosome contains 72 (the fewest protein-encoding genes). In general, genes are clustered in randomly distributed areas in the genome, with long regions of noncoding DNA in between.

Ancestral small duplications may explain this clustering. There might be subsequent divergence of duplicated genes' functions, and, in this process, some genes become nonfunctional copies, termed pseudogenes; some retain similar functions (e.g., the red-green color vision genes); and some develop novel functions as a result of small sequence changes or exon rearrangement.

The different (often computational) methods used to identify sequences as genes, and the subtypes of genes that are included, greatly affect the precise gene total. In addition to at least 23,411 protein-encoding genes, there are believed to be at least several thousand that code for RNA molecules but do not encode polypeptides. These RNA genes include at least 727 ribosomal RNA (rRNA) and 131 transfer RNA (tRNA) genes. A surprising number of other RNA genes are also now known to be present.

While their physiological roles are not yet as clearly understood as those of mRNAs, rRNAs, and tRNAs, a number of additional, intriguing RNA molecules are generally believed to be involved in the regulation of gene expression. These include, for instance, at least 2578 microRNA genes (described in detail later), 903 small cytoplasmic RNA (scRNA) genes, and 2019 small nuclear RNA genes (snRNAs). SnRNAs include RNAs that participate in splicing and a subclass of 1173 small nucleolar RNA (snoRNA) genes. Instead of being transcribed from separate genes, many snoRNAs are, interestingly, processed from introns spliced out from other genes. In contrast, scRNAs are usually found in complexes termed small cytoplasmic ribonucleoproteins (scRNPs), in association with cytoplasmic proteins. An example is the so-called signal recognition particle.

MicroRNAs (or miRNAs) are short single-strand RNA molecules of 21–23 nucleotides that regulate the expression of other genes. It is believed that regulation is mediated by the binding of the miRNAs to mRNAs especially in the 3′ UTR. This can cause the degradation of these mRNAs or the prevention of their normal translation into proteins. Although miRNAs do not encode proteins themselves, the large number of reports on the use of miRNA profiles (like mRNA profiles) as biomarkers of specific disease phenotypes should produce improved diagnostic and prognostic information to clinicians. (See Section 3.4 of this chapter.)

3.3 GENE EXPRESSION

3.3.1 Transcription

The process of transcription can be subdivided into three stages: *initiation*, *elongation*, and *termination*. Studies in the last five years have shown that these three stages coincide with the three steps involved in mRNA processing: 5′ capping, splicing, and 3′ processing.

Initiation of transcription is controlled by transcription factors (TF), which form *initiation complexes* with other TFs and proteins to repress or stimulate the transcription of a gene. TFs in the cell have multiple functions in the regulation of many different genes; thus their role is entirely dependent on the context in which they are found. TFs associate with particular sequences to either repress or stimulate gene expression—for example, the TF TATA-binding protein associates with the TATA box element located about 20–30 bp upstream of the transcription start site (TSS), bending the DNA double helix ready for subsequent assembly of the initiation complex. This complex then positions RNA polymerase II (RNAPII) at the TSS. The addition of helicase allows the unwinding of the DNA at the TSS so that transcription by RNAPII can commence.

The elongation step is a continuation of the primary initiation step in that this is when transcription progresses and a transcript is synthesized from the template strand. The C-terminal domain of RNAPII becomes phosphorylated as elongation occurs. Subsequent to initiation, a mechanism known as mRNA capping occurs, in which about 20–25 nucleotides of DNA are transcribed. The cap structure is added to the 5′ end of the growing mRNA via a short series of enzymatic reactions activated by the phosphorylated C-terminal domain of RNAPII. The cap has multiple functions: one is marking the TSS and another is the maturation of the mRNA and its stability in the translation step of protein synthesis. The general TFs that form the initiation complex dissociate.

Following this, elongation factors bind, forming what is known as the *elongation complex,* which facilitates the progression of RNAPII along the DNA. It is this complex that synthesizes the transcript. As elongation progresses, splicing factors are subsequently recruited. Co-transcriptional splicing of the nascent transcript occurs as it grows in length, and the intronic sequences are removed. Finally, termination occurs where transcription by RNAPII and the elongation complex continues past the *polyadenylation signal*, where polyadenylation factors assemble and catalyze cleavage of the transcript. The processed transcript is now prepared for export from the nucleus to the ribosome for translation.

As described, transcription and processing of mRNA, although two different processes, have been observed to occur concurrently and it has been substantiated that they are in fact dependent on one another, allowing the nascent transcript to be processed as transcription completes and increasing the efficiency of gene transcription.

3.3.2 Translation

Translation is the process by which a protein is synthesized by the assembly of amino acids into polypeptide chains according to the “code” of the mRNA sequence. This synthesis requires interaction between mRNA, transfer RNAs (tRNAs), ribosomal RNAs (rRNAs), and other proteins that form complexes. Translation occurs on structures in the cell called ribosomes that are composed of rRNA molecules and proteins. The mRNA is attached to the ribosome via the

5′ cap and is read in a 5′-to-3′ direction. The amino acids to be added are coded by codons of three base pairs in the mRNA sequence. These mRNA codons are not directly recognized by amino acids; in fact, tRNAs molecule act as adaptors, recognizing both mRNAs and amino acids and bringing them together. In the ribosome, tRNAs align an amino acid, which is attached to the 3′ end of the molecule, corresponding to the codons of the mRNA by virtue of complementary base pairing with the anticodon loop of the tRNA.

This codon-anticodon base pairing and the attachment of the correct amino acid at the 3′ end ensure accurate amino acid incorporation in the resulting protein molecule. The ribosome scans along the mRNA to which it is bound, and translation begins at specific sites, also known as initiation sites, coding for the amino acid methionine (most commonly the AUG codon). In the ribosome structure, there are three sites available for tRNAs to bind: the peptidyl site (P site), the aminoacyl (A site), and the exit site (E site). The first tRNA, the initiator, binds to the P site; the next tRNA is then brought to the A site to bind by an elongation factor that is attached to a guanosine triphosphate (GTP) molecule.

As the tRNA is incorporated into the A site, the GTP on the elongation factor is hydrolyzed to guanosine diphosphate (GDP) and released. Subsequently, a peptide bond forms between the initiator tRNA and the second tRNA. The methionine is thus transferred to the second aminoacyl tRNA. The ribosome then reads three bases along the mRNA molecule, moving the second tRNA to the P site and the uncharged tRNA, which no longer carries an amino acid, to the E site. The A site is now available for the next tRNA to pair via codon-anticodon interaction and for the reaction to occur again, thus incorporating the next amino acid. Elongation stops when a stop codon in the mRNA is reached (UAA, UAG, or UGA) because there are no tRNAs with anticodons that pair with such codons. Instead of tRNA binding, a release factor recognizes the site. As a consequence, the mRNA and tRNAs are released from the ribosome, the completed chain of amino acids also dissociates, and the translation sequence can begin once more. (See [3], *Essential Medical Genetics*.)

3.4 GENE REGULATION

All nucleated cells of an individual have an identical genome, yet at any one time in many cell types only a small fraction of the total genes are expressed at a significant level. Moreover, during the differentiation of cells and tissues, the relative pattern of expression needs to vary widely and permit the synthesis of different proteins in each cell. These demands may change, for instance, in development and in the cellular response to local growth factors or circulating hormones. Areas of DNA flanking each gene play an important role in regulating transcription and hence synthesis of each protein. Immediately upstream of the gene is the promoter, which is involved in the binding of RNA polymerase II to the DNA template strand. Promoters for RNA polymerase II are usually several hundred nucleotides long and often contain a consensus sequence, 5′-TATAAA-3′ (the TATA box). This sequence, usually located around 25 bp upstream of the transcriptional start site, binds, via the so-called TATA-binding protein (TBP) subunit of TFIID, to a series of general transcription factors (e.g., TFIIA, TFIIB, TFIID, TFIIE, TFIIF, and TFIIH), which are relatively abundant proteins used to initiate the transcription of nearly all mRNAs.

Basal transcriptional efficiency is commonly aided by the presence of other upstream short-consensus regulatory sequences in the promoter region. These often include multiple copies of the so-called GC box, which binds the ubiquitous transcription factor SpI and the CAAT box, which is typically located 75 bp upstream of the transcriptional start site and to which the transcription factors CTF and CBF bind.

The activity of many promoters is modulated (increased or decreased) by one or more enhancers—generally short (less than 20–30 bp) sequences that bind *specific (i.e., tissue-restricted) transcription factors*. Most enhancers can function whether on the coding or the noncoding strand of DNA and can be located, in either orientation, up to several hundred kilobases from their target promoter. Most of them are active only in specific cell types and thus play a central role in regulating the tissue specificity of gene expression. Silencers are similar sequence elements that, in contrast, inhibit transcription of the associated gene.

There are several chromosomal deletions that can deleteriously affect developmental gene expression and thus cause clinical syndromes despite being located far upstream or downstream of the important genes. The presence of intergenic enhancers and silencers is likely to explain, in many cases, the pathogenicity of such deletions. Large numbers of specific transcription factors and their interaction at individual enhancers allow complex patterns of gene activation, such as during tissue differentiation and with physiological (or pathological) receptor signaling. Interactions between the proteins bound to enhancers and those bound to the promoter sequences are probably permitted by the intervening DNA's formation of long loops.

Approximately 80% of genes are expressed only at specific times and places (e.g., insulin in the pancreatic islet β-cells). The remaining 20%, called housekeeping genes, are expressed in all tissues, generally fulfill basic metabolic needs, and account for 90% or more of the genes expressed in any particular cell type. The majority of housekeeping genes and about 40% of tissue-specific genes possess CpG islands near their 5′ ends. CpG islands are about 1 kb in length and contain a high proportion of 5′-CG-3′ dinucleotide pairs, generally indicated as "CpG" (i.e., "C" for cytosine, "p" for phosphate, and "G" for guanine) to distinguish

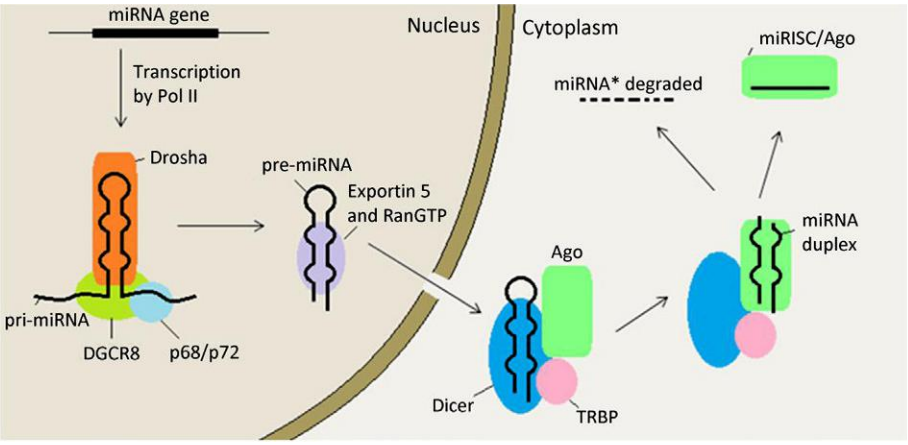

FIGURE 3.3 **Schematic of miRNA biogenesis.** Pri-miRNA transcripts are subject to two cropping events. First, Drosha, in the microprocessor complex, cleaves the mRNA-like pri-miRNA to give a pre-miRNA structure. This structure is recognized by exportin-5 and, together with RanGTP, transports the pre-miRNA to the cytoplasm via nuclear pores. In the cytoplasm the second cleavage event occurs and is catalyzed by Dicer in the RLC. This generates a miRNA: miRNA* duplex that is separated by Ago protein. The miRNA* strand or passenger strand is degraded; however, the guide strand is loaded into Ago, and other members of the RISC complex are recruited. miRISC carries out miRNA-mediated silencing of target mRNAs. *Source: Adapted from* [7] *with information from Kim et al.* (2009).

them from G hydrogen-bonded to C in opposite DNA strands. Generally, cytosine residues in these CpG dinucleotides are methylated. There is usually a lack of methylation, however, in CpG islands associated with active neighboring gene expression.

Although the bulk of gene expression regulation probably occurs at the transcriptional level, the regulation of a gene's activity may also occur later. For example, there may be (1) alternative splicing of the mRNA to produce different gene products (e.g., calcitonin or calcitonin gene–related neuropeptide) or (2) an altered rate of translation or degradation of the protein.

Mutations in a gene's regulatory sequences (such as its promoter region) can occur and may result in no gene product (e.g., some patients with β-thalassemia), abnormal continued expression of a fetal gene product (e.g., hereditary persistence of α-fetoprotein or hemoglobin F), or anomalous patterns of gene expression (e.g., ectopic expression of creatine kinase).

There are now important internationally agreed conventions regarding the nomenclature, for publishing and clinical reporting, of human gene mutations and their effects on proteins (see [3]).

3.4.1 Gene Regulation by miRNAs

MicroRNAs (miRNAs) are small noncoding RNAs of ~22 nt that play an essential role in gene regulation by binding to the 3′ UTR of protein-coding mRNAs, and by initiating post-transcriptional silencing by repressing translation and/or causing mRNA degradation. There are currently 2578 mature miRNAs reported in miRBase. As each miRNA can have multiple targets, collectively they are thought to directly regulate approximately a third of human genes (see [8,9]). There are high levels of conservation in miRNAs between organisms, particularly bilaterian animals, suggesting that they play a vital role in multiple species. The expression pattern of miRNAs varies between cell types and over time; thus, it implicates them heavily in development and other biological processes. Additionally, deregulation of miRNA expression has been shown to have pathological consequences.

Genes encoding miRNAs are located throughout the genome, although many are found situated close together under the control of a single promoter region. Normally, miRNAs or miRNA clusters are found in introns of protein-coding genes or in noncoding DNA; however, some have been found in exons of protein-coding genes that rely on alternative splicing for their expression. miRNA gene transcription is usually carried out by RNA polymerase II (Pol II), although in rare cases Pol III is used. This places the majority of miRNA genes under the control of transcription factors associated with Pol II, along with many other transcription factors, and thus Pol II controls the expression of miRNAs in different cell types and during development.

Primary transcripts (pri-miRNA) must undergo processing before the mature functional miRNA can bind target mRNAs (Figure 3.3). The pri-miRNA structure has a 5′ cap and a poly(A) tail, and it usually contains at least one long (~30 bp stem) imperfectly matched hairpin loop with single-stranded segments on either side of its base (see [7,10]). The pri-miRNA structure is recognized by the microprocessor complex, which consists of an RNase III enzyme referred to as Drosha, and an RNA-binding protein referred to as DiGeorge syndrome critical region gene 8

(*DGCR8*). Additional co-factors such as RNA helicases p68 and p72 are required for biogenesis of specific miRNAs. DGCR8 recognizes the junction between the single-stranded RNA and the double-stranded hairpin and acts to guide Drosha to cleave ~11 bp away from it. The truncated hairpin product of this reaction is known as precursor miRNA (pre-miRNA) and is characterized by a 3′ overhang created by Drosha cleavage. Microprocessor activity is thought to occur co-transcriptionally and before splicing of the coding RNA, but does not inhibit splicing activity.

Exportin-5 recognizes the 3′ overhang and the double-stranded stem of the hairpin and binds pre-miRNAs. Together with Ran-GTP, it exports pre-miRNA from the nucleus to the cytoplasm. Once in the cytoplasm, pre-miRNA dissociates from exportin-5 and is recognized by the RISC loading complex (RLC), which consists of a second RNase III enzyme, Dicer, TAR RNA-binding protein (TRBP), and members of the argonaute (Ago) protein family. Dicer recognizes the 3′ end of the pre-miRNA and cuts both strands of the hairpin ~22 nt away from the 5′ and 3′ ends, thus removing the terminal loop and creating an miRNA duplex. TRBP function is not yet fully understood, although it is possible that it stabilizes the RLC or plays a role in proper RNA-induced silencing complex (miRISC) formation. Only one strand of miRNA is loaded onto an Ago protein to form part of the RISC, while the other strand, termed miRNA*, is degraded. The RISC complex facilitates the miRNA-mediated repression of target mRNAs, which will be discussed in more detail later.

The properties that determine which strand enters the miRISC are not fully elucidated. Thermodynamic stability of the ends of both miRNA strands and the positions of mismatches in the duplex are thought to play a role; however, there are cases where both strands are used as mature miRNAs and where the relative frequency of the strand utilized is similar. Heterogeneity also affects the frequency of specific miRNAs. It is brought about by Drosha and Dicer cleavage activity that is not absolutely specific, thus generating strands of differing lengths and ends. The specificity of the miRNA for its target can be altered if there is a change at the 5′ end of the miRNA because this can affect the seed. The seed is the region of the miRNA that binds specifically to targets in the 3′ UTR of mRNA and is typically situated in nucleotides 2–7 of the miRNA.

The processes just described form the canonical miRNA biogenesis pathway; however, there are noncanonical methods of miRNA maturation. Mirtrons are spliced from the transcribed intron of an mRNA and directly form a pre-miRNA structure, thus making the microprocessor stage of biogenesis redundant, but the relevance of this type of miRNA is not yet understood. There also exists at least one miRNA, miR-451, that can skip the Dicer step in maturation. Pre-miR-451 can directly bind Ago2 and is cleaved in a two-step process to form miR-451 (see [7]).

3.4.2 mRNA Targets

In plants the full length of a miRNA binds to its target in mRNA molecules, with pairing at every, or nearly every, base. However, in animals full complementarity is an infrequent occurrence. Instead, as mentioned previously, the seed (nucleotides 2–7) of the miRNA is the region found in complete or almost complete Watson-Crick pairing with the mRNA's target site. Targets are located in the 3′ UTR in animal mRNA and are nonrandomly distributed; the majority of are located at the 3′ and 5′ ends of the 3′ UTR. In addition, multiple target sites are often found in one 3′ UTR, and it is thought that miRNA binding at more than one site can act to further increase mRNA repression (see [11]).

While seed pairing is essential, the level of complementarity can vary slightly depending on the target sequence; thus, the different interactions can be classified as canonical, 3′-complementary, and 3′-supplementary (Figure 3.4). Canonical sites are naturally the most abundant and conserved site types. First is 7mer-1A, which has seed pairing at positions 2–7 with an adenine opposite position 1 of the miRNA. The adenine increases the repression by miRNAs. Second is 8mer, which has the same composition as 7mer-1A but with an additional pairing at position 8 of the miRNA. Third is 7mer-m8, which has pairing with the seed at positions 2–8 but does not have an adenine opposite position 1. Both the 3′-supplementary and 3′-compensatory sites involve pairing at downstream 3′ sites in the miRNA (nucleotides 13–16). Where the 3′ site is additional to normal 7mer/8mer binding, it is supplementary; however, this additional pairing has been shown to have little effect on the efficiency of silencing. The rarely seen compensatory 3′ pairing is so-called because it compensates for a 1-base mismatch in the seed region. Although their silencing effect is minimal, 6mer sites can also been found.

Bartel [12] assessed different factors in interactions between miRNA and mRNA that affect repressive action. This study found that 8mer sites are the most effective of all basic sites, while multiple sites in a single 3′ UTR have the greatest overall efficacy. It was also reported that increased AU content of the region surrounding the target site is directly correlated with repressive effect.

Finding target mRNAs is important for understanding the cellular processes in which specific miRNAs are involved. Generally, computational methods are used to identify possible candidate targets that are then verified experimentally. Computational target prediction is complicated by the small and variable region of complementarity between miRNAs and their targets in animals (see [13]). Almost all such programs rely on seed complementarity in some form for selection of targets from 3′ UTR datasets. However, given the small size of the seed region, this complementarity produces an overwhelming number of results and so a number of programs incorporate additional

parameters to narrow the search. These criteria include conservation of the site between organisms, the presence of more than one target in close proximity, the structure of the 3′ UTR, and the thermodynamic stability of the miRNA–mRNA interaction. As each of these programs has its own limitations regarding specificity and sensitivity for target detection, it is often suggested that combinations of more than one algorithm be used to produce more reliable results. The expression patterns of miRNAs and the selected targets should then be compared using array technology; targets that show an inverse correlation with the level of miRNA should be experimentally validated (see [11]).

3.4.2.1 *Mechanisms of Silencing*

Where there is almost full complementarity between miRNAs and mRNAs, Ago2-mediated cleavage of the target mRNA can occur. However, as discussed, full complementarity is rare, and so translational repression was originally thought to be the silencing mechanism employed by animal miRNAs (see [14]). Nevertheless, studies on mRNA levels have shown that, in coordination with miRNA depletion, there is an increase in target mRNAs. Likewise, an increase in miRNA levels results in a decrease in target mRNAs [14]. It has now been shown that mRNA degradation may in fact be the predominant mechanism by which silencing is carried out. Currently, there is still much debate as to whether translational repression or mRNA destabilization is the initial event triggered by miRNA-facilitated miRISC activity. Furthermore, the exact alterations and reactions that are catalyzed by the miRISC and that cause silencing are yet to be determined. Despite this, some key components have been identified and will be briefly discussed.

As mentioned previously, after the mature miRNA is loaded into an Ago family protein, it forms part of the miRISC. Another member of this complex is TNRC6, which contains GW repeats along the length of the protein and has been shown to associate with Ago through its N-terminal region (see [15]). TNRC6 has multiple paralogs (TNRC6A, -B, and -C) and is conserved across species—for example, GW182 in *D. melanogaster*. Studies have assessed the importance of various domains in TNRC6 with regard to mRNA silencing and its interactions with other proteins (Figure 3.5). The C-terminal silencing domain (SD) is essential for silencing and contains sites for interaction with cytoplasmic poly(A)-binding protein (PABP); NOT1, which is a member of the CCR4-NOT complex; and PAN3,which is part of the PAN2-PAN3 complex [15].

The CCR4-NOT complex is a deadenylase, shown to bind TNRC6 through NOT1 interaction with tryptophan repeats found in M1, M2, and the C-terminal. PAN2-PAN3 is also a deadenylase and interacts with the M2 domain in

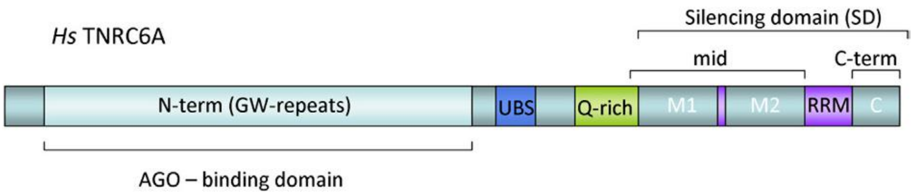

FIGURE 3.5 **Functional domains of the human TNRC6 protein.** UBA: ubiquitin associated domain. Q-rich: glutamine-rich region. M1/M2: two sections of the mid-region separated by PAM2. PAM2: PABP interacting motif 2. RRM: RNA recognition motif. *Source: Drawn from* [14].

TNRC6. Deadenylation of the poly(A) tail of target mRNAs leads to deadenylation-dependent mRNA degradation by exonucleic action. The role of CCR4-NOT in mRNA degradation has been confirmed by experiments showing that the tethering of this complex to target mRNAs, thus bypassing the need for miRNA-mediated interactions, nevertheless causes deadenylation and subsequent mRNA degradation (see [15,16]). The CCR4-NOT complex has also tentatively been implicated in translational repression, as tethering to mRNA targets without a poly(A) tail still allows for silencing without deadenylation-driven degradation. Conversely, removing subunits of CCR4-NOT leads to some decrease in the silencing effect on mRNAs without a poly(A) tail. Other studies have uncovered evidence against CCR4-NOT participation in translation repression, showing that its depletion still allows for some silencing by translation repression but that mRNA degradation is inhibited (see [15]).

PABP binds to mRNA poly(A) tails and also associates with eukaryotic translation-initiation factor 4F (eIF4F) complex and the 5′ cap to generate a circular mRNA structure that is stable and efficiently translated. TNRC6 can also interact with PABP via the PAM2 domain, and disruption of this interaction leads to a decrease in the silencing ability of miRISC, even when TNRC6 continues to interact with deadenylases [15]. The interaction with TNRC6 causes PABP to disassociate from the poly(A) tail before the initiation of deadenylation and at the same time that Ago association with mRNA is observed (Figure 3.6; see [17]). This suggests that miRISC coordinates the removal of PABP from the poly(A) tail and allows for CCR4-NOT deadenylation. PABP has also been implicated in the recruitment of miRISC to target miRNAs. The fact that the presence of a poly(A) tail enhances silencing but is not strictly necessary for it indicates that, while PABP plays an important role, it may not be essential for silencing under all conditions.

The removal of PABP from the poly(A) tail may also disrupt EIF4F complex binding and thus negatively affect translation initiation. A study by [18] showed that the EIF4F complex is required for repression of mRNAs with a structured 5′ cap. Additionally the study assessed the specific component involved in EIF4A2 by knockdown of each member of the complex. EIF4A2 is thought to unwind the 5′ secondary structure of mRNA for translation. Meijer et al. [18] showed that EIF4A2 is bound to repressed mRNAs and also immunoprecipitates with NOT7, a member of the CCR4-NOT complex. EIF4A1 is normally found in excess of the A2 form and is thought to be involved in normal translation activity, whereas repression-induced binding of EIF4A2 inhibits translation. However, this interaction should be further investigated to confirm the role of this protein in translational repression.

While it is obvious that the precise mechanisms of both mRNA degradation and translational repression are as yet unclear, key components in both pathways have been identified. Huntzinger et al. [15] proposed that the minimal requirements for repression are Ago, TNRC6, PABP, and the deadenylation complex, and that other factors may regulate or enhance the repression activity.

3.4.3 Chromatin Modifications and Gene Expression

Particular residues present in histone tails are often subject to post-translational modification. For example, the basic residues lysine (with mono-, di- or tri-methylation), arginine (mono-, symmetrically, and asymmetrically di-methylated), and histidine are commonly methylated (see [6,19]), whereas serine, threonine, and tyrosine are often phosphorylated. Depending on the position of the modification, this can have different effects on overall chromatin structure; for example, the tri-methylation of lysine 27 on histone 3 (H3K27me3) is associated with the closing of the chromatin, and therefore transcriptionally silent, regions. However, despite methylation being associated with silencing, this is not always the case. Methylation of lysine 4 on H3 (H3K4) has been observed to have the opposite effect. The many types of modifications and the histone tail residues with which they are associated are summarized in Figure 3.7.

3.4.4 Nucleosome Positioning and Occupancy

For the binding of TFs and other factors essential for transcription to take place, regions of heterochromatin must be remodeled and the nucleosome positions moved [20]. The positioning of nucleosomes controls many DNA

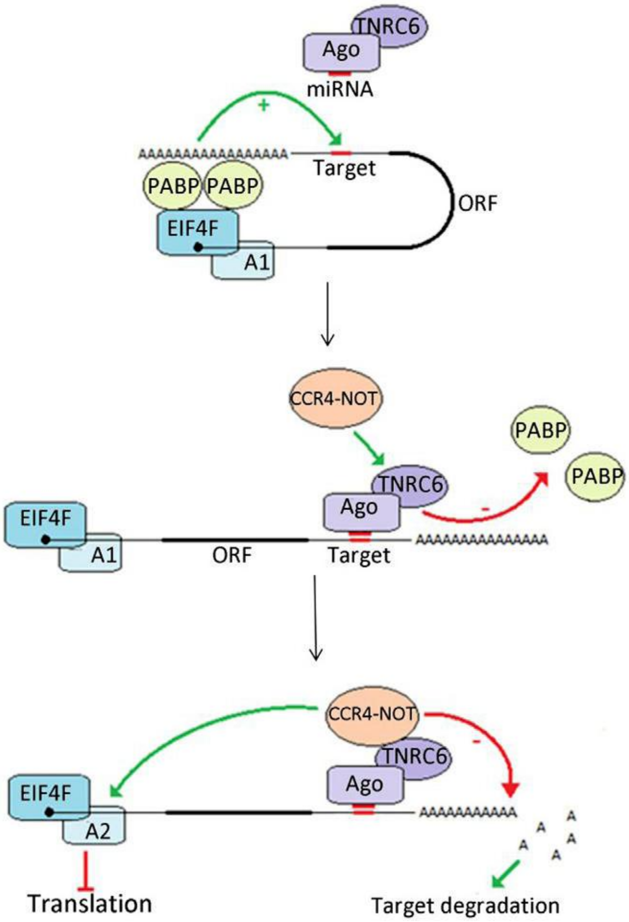

FIGURE 3.6 **Proposed mechanism of mRISC-mediated mRNA destabilization and translational repression.** PABP is bound to the poly(A) tail of the target mRNA and is associated with the 5′ cap through the EIF4F complex, creating a loop that is stable for translation. PABP aids in recruiting mRISC via TNRC6 binding. It dissociates from the poly(A) tail upon mRISC binding to the target, causing the mRNA loop to break. TNC6 recruits the CCR4-NOT complex by binding NOT1. CCR4-NOT causes deadenylation of the poly(A) tail, which destabilizes the mRNA and triggers exonuclease-mediated mRNA degradation. Additionally, mRISC binding causes EIF4A2 to bind the 5′ cap instead of the A1 isoform, which inhibits translation of the mRNA.

interactions, including determining which sequences can undergo processes such as transcription or be repaired (see [21]). Nucleosomes are not distributed evenly across the genome; some sequences are more likely to have dense nucleosome occupancy, while others (such as enhancer, promoter, or other regulatory sequences rich in poly A: T and C: G tracts) tend to have fewer such structures.

Some sequences have even been observed to be completely nucleosome-free. Other factors, such as DNA sequence, can influence the position of nucleosomes in particular regions (Figure 3.8). For example, more flexible DNA sequences rich in A and T dinucleotide interspersions (about every 10 bp) tend to come into contact with the histone octamer because they can bend around the protein core while more rigid sequences do not come into as close contact with the complex. The linker DNA regions interspersed between nucleosomes are also associated with more rigid sequences such as poly(A) tracts. Both positioning and occupancy determine which DNA interactions can take place. It is of note that nucleosomes inhibit protein interactions with DNA, although to varying extents depending on the interacting factor itself. For example, some TFs may bind to DNA even in the nucleosome structure, whereas other factors are incapable of initially interacting with DNA where nucleosomes are present without the aid of remodeling complexes.

There are two main mechanisms by which chromatin structure can be altered: the first, through covalent histone modifications by specific enzymes; the second, through ATP-dependent remodeling complexes. In the cellular context, these mechanisms work together in chromatin structure regulation.

3.5 GENOMIC VARIATION

Genetic differences in individuals within and between populations are responsible for human diversity, including traits such as eye and skin color and even disease susceptibility.

FIGURE 3.7 **Post-translational chemical modifications to histone proteins.** Phosphorylation of serine residues (purple dot) and acetylation of lysine residues (blue dot) occur on all four histones of the nucleosome. Ubiquitylation occurs on histones H2A and H2B. Methylation of arginine residues occurs on H3 and H4. On H3, many lysines are methylated. However, whether the methylation causes repression or activation depends on which lysine is modified; for example, H3K4 and H3K36, when methylated, are associated with activation, whereas methylation of H3K9 and H3K27 is implicated in silencing. *Source: Drawn using information from Allis et al.* (2006) [22].

Intra- and interpopulation variation has arisen over time as a result of, for example, mutation, recombination, and natural selection. Natural selection may occur, for instance, when alleles or sequences confer selective advantages for individuals carrying such variants—in response to, say, a particular environmental stress to which their population has been exposed. These allele frequencies vary within populations and between them. Different types of variation are found in the genome, ranging from cytogenetically visible changes involving whole chromosomes (e.g., trisomy 21) to single base pair alterations (single-nucleotide polymorphisms). Variations in genome structure and sequence can cause phenotypic variation, both pathogenic and nonpathogenic, by altering expression levels, protein function, or protein efficacy. Genetic diversity in terms of recently discovered submicroscopic variations will be discussed in this section.

3.5.1 Single-Nucleotide Polymorphisms

Single-nucleotide polymorphisms (SNPs) are single base pair substitutions that mostly result from replication errors not repaired by DNA repair machinery, although they can occur by other means. SNPs can be located throughout the genome, but they are more frequently found in noncoding regions than in coding regions because of selective pressure on protein-coding domains. This means that alleles that confer an advantage are usually conserved.

3.5.1.1 Effect of SNPs on Gene Expression

SNPs in a coding region can be synonymous; that is, that they do not result in a change in amino acid. Alternatively, they can be nonsynonymous SNPs of two types. Missense mutations cause a substitution of a single amino acid, whereas nonsense mutations change an amino acid to a stop codon, thus truncating the protein. Type and location can determine the level of phenotypic effect that a SNP produces, with nonsense mutations more likely to be pathogenic and synonymous SNPs more often neutral [23]. The effect of missense mutations depends on the location of the altered amino acid in the protein as well as the nature of the substitution.

SNPs in noncoding regions may still affect gene expression, particularly if located in a regulatory region, as this can affect the binding of regulatory subunits or transcriptional machinery (see [23]). Also, SNPs located in introns may cause variants by altering gene splicing. Many small non-coding regions of the genome are transcribed and affect post-transcriptional regulation of gene expression—namely, small noncoding RNAs (as described in the section on gene regulation). SNPs in these regions or their target regions in mRNAs can also cause variation in gene expression.

3.5.1.2 Linkage and Haplotype Blocks

Variation in the SNP profile of individuals and populations is brought about by recombination, which is the exchange of material between chromosomes that can occur during meiosis when crossovers are formed between homologous regions (Figure 3.9). Linkage describes the principle that loci closer together in the genome are more likely to be inherited together because there is less chance of a recombination event occurring between them. A haplotype is a set of alleles inherited together. Generally, recombination will lead to new haplotypes, and at similar frequencies between equally spaced loci. However, linkage disequilibrium leads to some alleles remaining together through multiple generations because recombination does not occur at the expected frequency. This can be due to selective advantage or to one

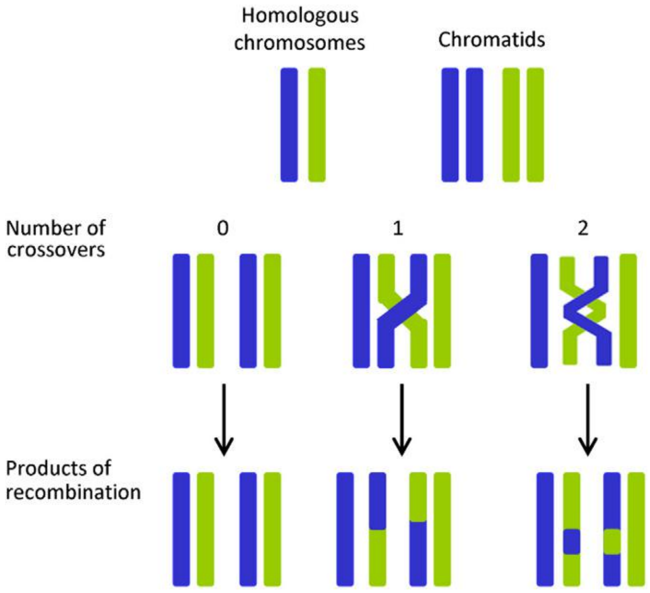

FIGURE 3.9 Recombination during meiosis. Pairs of chromosomes are held together during prophase I of meiosis by crossovers that form between homologous sites. When these pairs are pulled apart, there can be an exchange of material, causing a new combination of alleles to be generated on one chromatid of each pair. After meiosis II, gametes with four haplotypes are formed.

allele being relatively new and so there has been insufficient time for recombination to occur (see [3]).

There are specific locations in the genome that are more prone than surrounding regions to recombination events. As a result, blocks of sequence between these hotspots tend to exhibit linkage disequilibrium and are inherited as intact units, termed haplotype blocks. For each haplotype block, there can be multiple haplotypes, each containing a different SNP combination.

The size and frequency of haplotype blocks vary between populations, and this can be used in population origin studies. The greatest amount of haplotype diversity is seen in African populations. In contrast, repeated founder effects during migrations have led to less haplotype variation in other populations. Larger conserved blocks indicate a more recent ancestry because there has been less time for recombination to occur; again, this is consistent with the generally shorter nature of blocks seen in African populations, and it may also be due to selective advantage conferred on a haplotype. Haplotype blocks can be useful in disease studies, as mutations located in a SNP haplotype block can be associated with a particular haplotype. Thus, SNPs can be used to narrow the search for the block that contains the disease-causing mutation, by assessing the frequency with which key identifying SNPs (tag-SNPs), in different blocks associate with the disease.

3.5.2 Copy Number Variants

Copy number variants (CNVs) are not as well characterized as SNPs, but they are believed to be, in many cases, functionally significant in human disease and variation. CNVs are a form of structural variation that arises from dosage effects (relative numbers of each sequence) or potentially from the interruption of sequences. They are distinct from SNPs as they range in size from kilobases to megabases. Their occurrence is due to events such as deletions, duplications, or insertions in particular regions known to be spread throughout the whole genome. In fact, in a study of 270 individuals of European, Asian, and African ancestry, 1447 CNV regions were found by Redon et al. (2006) [24], including associations with genes, disease loci, and functional elements that contribute to transcription. Particular CNVs are also known to be associated with human diseases such as Parkinson's and Alzheimer's.

3.5.2.1 Mechanisms of CNV Formation

The sequence context of CNVs has been examined for clues about the mechanisms involved in the formation of CNV regions. Homologous recombination is believed to be one mechanism, occurring between sequences that are very similar but not allelic. Duplications of near identical (>90%) sequences, known as segmental duplications, as well as deletions, have been observed and are thought to have arisen in this way. Other genomic sequence homologies, such as Alu elements (sequences dispersed across the whole genome) are also believed to play a role in the promotion of nonallelic homologous recombination. Orientation, size, and sequence similarity are factors expected to have an effect on the likelihood of such mechanisms occurring and causing rearrangements. The outcomes of combinations of these mechanisms and factors can be seen in Figure 3.10.

3.5.2.2 Population Genetics of CNVs

Data on particular CNVs found in the population studies carried out by Redon et al. (2006) show that variants are often population-specific. The distribution of CNVs within and between populations is determined by mutation and selection among other factors.

The human salivary amylase gene *(AMY1)* is one of the most polymorphic of the human CNVs, with the number of copies of it varying from 6 to 15. Such an adaptation is believed to have arisen and subsequently been selected for because of high-starch diets in some populations, improving the breakdown and digestion of starch by amylase into maltose sugar.

3.5.2.3 Relationship of CNVs and Transcriptional Regulation

The majority of CNVs, like SNPs, are found in noncoding regions of the genome or in relatively gene-sparse regions. Changes in copy number can have an effect on gene activity directly, in a relative dosage–sensitive manner, or indirectly, by interrupting sequences that are essential in transcriptional regulation—for example, acting as activators or repressors of transcription (Figure 3.11). Thus, as with other forms of genetic variation (e.g., SNPs), differences in protein levels that arise from CNVs by direct or indirect mechanisms may disrupt cellular or tissue homeostasis and may have a role in human disease. Conversely, the threshold level of change that is required to confer a phenotypic effect may not be reached by these mechanisms, and thus some CNVs may result in no observable effects in an individual or on those carrying the variant [25].

The study of CNVs and their effects on human variation and disease is still very much in its infancy; however, from the findings so far it is likely that their impact on our understanding of variation and, potentially, the molecular mechanisms that confer risk to disease phenotypes will be highly significant [26].

3.5.3 The ENCODE Project and the Characterization of Human Variants

working under the auspices of the National Human Genome Research Institute (NHGRI). Its goal is to identify regions of the genome that are active or that have functional significance. So far, ENCODE has estimated that, as much as 80.4% of the genome may have biochemical (and possibly also biological) activity, using evidence from at least one cell type (out of the 147 cell types used) and using at least one experimental or computational system. Specifically, it is reported that 8.5% of the genome consists of protein-binding sites for transcription factors. ENCODE researchers have also calculated that the total number of enhancer elements in the human genome, according to their data, is 399,124 and that there are, on average, 6.3 alternative transcripts per locus.

Many investigations of complex or multifactorial disorders have involved genome-wide association studies identifying a large number of SNPs conferring disease susceptibility that lie outside the coding regions of genes. Variants that are associated with human diversity (SNPs, CNVs, epigenetic changes) have also been characterized.

The enormous volume of work undertaken for the ENCODE project has resulted in many published papers and datasets. These data and published conclusions (particularly concerning the proportion of the genome calculated to be biologically functional; see [27]) have provoked much interesting debate and even some considerable controversy internationally.

3.6 CONCLUSION

There are multiple complex and dynamic mechanisms, including histone modification and nucleosome repositioning, by which the genome's compacted structure is maintained and modified. These mechanisms, together with the actions of RNA genes (e.g., miRNAs) and the consequences of interindividual genomic sequence variation (e.g., SNPs and CNVs) affect gene expression in ways that are incompletely understood but include altered transcription, splicing, and translation. Major international research projects, such as ENCODE, currently aim to elucidate the possible biological functions of the many noncoding regions of the genome. There are many completed and ongoing genome-wide association studies, together with an increasing abundance of high-resolution array comparative genomic hybridization and whole genome sequencing data. These datasets encompass numerous SNPs and CNVs located outside protein-coding sequences in genomic regions of uncertain biological significance [2,25,28–31]. Studies into the functions of such regions is of considerable importance, from both biological and clinical perspectives.

4.1 OVERVIEW

In a single organism, there are a huge variety of cell types that each perform specific, and often unique, tasks. Fibroblast cells are responsible for generating the stroma in tissue. Cardiac muscle is electrically sensitive and, through coordinated contractions signaled by electrical pulse, propels blood through the blood vessel. Neuronal cells are also electrically sensitive, but electrical activity instead activates synaptic connections with other cells. Parietal cells produce a potent gastric acid in the stomach to facilitate digestion of food. All of these cells are derived from a common fertilized egg cell and all share the same DNA sequence; remarkably, however, each has a vastly different purpose and subsequently a vastly different gene expression program.

Epigenetics refers to any heritable change in genome function that does not result in a change to the DNA sequence itself. Information can be heritable through cell division and/or organismal generations. Epigenetics has a strong association with a variety of diseases; identification of the perturbations of epigenetic marks may therefore act as a biomarker for early disease identification.

Individuals in a population vary not only in terms of DNA but also in terms of epigenetics. Thus, their response to treatment or their disease progression can be dependent on the epigenetic modifications they possess. For this reason, individual variation in terms of epigenetics may affect patient outcome and so it is important to be able to identify patients who may respond more or less favorably to specific treatments because of their epigenetic status. Epigenetic modifications are generally stable, but they can also be reversed, leading to the potential for personalized treatment to reverse undesirable epigenetic states or to introduce beneficial ones.

This chapter focuses on the influence of DNA methylation, histone variants, and histone modifications as sources of epigenetic information. (For conciseness, the chapter does not cover other epigenetic mechanisms such as noncoding RNA/microRNAs, chromosome structural conformation, prions, or RNA feedback loops.) Methods of measuring and manipulating epigenetic marks are discussed. A summary of the known effects of and disease relationships to epigenetics and prospects for epigenetic therapies are provided.

4.2 DNA METHYLATION

DNA methylation is the addition of a methyl group to cytosine (C) or adenine (A) DNA nucleotides. Most organisms are capable of methylating cytosine bases (methylcytosine), which leads to methylation being frequently referred to as the "fifth base"; however, methyladenine is generally regarded as a bacterial DNA feature. Methylation is a relatively stable and heritable modification of DNA nucleotides that serves to regulate a number

Handbook of Pharmacogenomics and Stratified Medicine. http://dx.doi.org/10.1016/B978-0-12-386882-4.00004-9

of cellular functions—for example, during cellular differentiation. Although, in specific cases, DNA sequence can vary between cell types (i.e., immune class switch recombination), in the majority of cases DNA is identical across all of an organism's cells. In contrast, DNA methylation frequently varies between different host organism cell types and, although relatively stable, is potentially reversible.

Because the focus of this book is on pharmacogenetics, this chapter concentrates on the methylation of cytosine nucleotides that occurs in mammalian genomes, with an emphasis on human molecular biology.

Methylation occurs predominately at CpG dinucleotides in mammalian genomes, where a CpG site is a cytosine immediately followed by a guanine when reading 5′ to 3′ on a linear piece of DNA—the "p" represents the single phosphate linking the two nucleotides. Because a CpG is a palindromic sequence, it has a complementary pair on the opposing strand.

CpG sites in human genomes are heavily methylated—on average, 70% of CpGs in primary human cells. Cytosines in any other configuration (CHG and CHH sites, where "H" refers to any base other than guanide) are methylated much less frequently (~0.1%). A methylated CpG (meCpG) is selected against in the genome because of hypermutability resulting from spontaneous deamination of the cytosine. While deamination usually forms a uracil—a nucleotide not normally found in DNA that can be detected and replaced by DNA repair enzymes—the deamination of methylated cytosines forms a thymine, which is commonly found in DNA and is less easily detected. Nonetheless, Thymine-DNA glycosylase (TDG) is an enzyme that attempts to repair such CpG mutations, but it is not fully effective.

Consequently, CpG dinucleotides occur at a rate of only about 1% in the genome; this is around one-quarter of what would be expected by chance. Surprisingly, however, there are concentrations of CpG dinucleotides in the genome, known as CpG islands. These tend to be located near gene transcription start sites (particularly at housekeeping genes), in enhancers, and occasionally in genes themselves. The cut-off for defining a CpG island usually includes a minimum size, a minimum percentage of G+C nucleotides, and a minimum ratio of observed-to-expected CpG content compared to total G+C content. Cut-offs for GC content and Obs/Exp ratio are often based on historical values of 50% and 0.6, respectively, with a minimum size of 200 bp [1].

In normal human cells, CpG islands are generally unmethylated—in stark contrast to the 70% methylation seen genome-wide. As a result, they are usually explained as the result of selective pressure for high CpG content in a region and/or the result of CpGs being unmethyated for another reason, such as gene regulation.

4.2.1 Effects of DNA Methylation

DNA methylation has been implicated in the regulation of gene expression; however, the exact mechanism by which this process occurs is still poorly understood. The methylation status of CpG islands located near the transcription start site of a gene has been shown to be linked to the expression level of the gene, and it is believed that lack of methylation at CpG islands permits expression while increased methylation limits expression to low levels. Although the vast majority of CpG islands in normal cells are constitutively unmethylated [2], a number become methylated in some cases, and this methylation is associated with transcriptional silencing [3]. Focal methylation and silencing of some tumor suppressor genes [4] have also been observed in cancers [5]. However, methylation may be a secondary effect that occurs after gene silencing [6] rather than the causative agent. Similarly, loss of methylation at oncogenes has been associated with reactivation in tumors [7].

Like the genome-wide tendency toward high levels of CpG methylation, gene bodies tend to be highly methylated as well. The relationship between gene expression and gene body methylation is difficult to decipher because, while some cell lines exhibit a positive correlation between gene expression and gene body methylation, this relationship has been shown to be nonmonotonic [8]. Specifically, genes with the lowest and highest levels of expression have been shown to have the lowest level of methylation, while genes with intermediate levels of expression have been shown to possess the highest level of methylation in the gene body.

One proposed role for the methylation of gene bodies is the suppression of spurious transcription initiation. A negative correlation exists between levels of methylation in gene bodies and the initiation of intragenic transcripts at the SHANK3 locus [9]. It is unclear if this correlation is a mechanistic result of the methylation or if the methylation and the suppression of spurious intragenic transcription are both the result of a common chromatin structure [10].

Methylation has been associated with the suppression of DNA repeat transcription and retrotransposition. Transposable elements [11] are DNA sequences that can duplicate themselves in the genome via an RNA intermediary (i.e., class I elements) or change their position within the genome via transposase enzymes (i.e., class II elements). Transposable elements are potential mutagens and can damage the genome by insertion into functional genes or by leaving unrepaired gaps from the location that the element left [12]. Methylation has been shown to suppress transcription of endogenous retroviruses [13], and methylation of retrotransposons may be necessary for mammalian viability [14].

Although methylation of specific CpG sites is capable of suppressing transcription of LINE transposable elements [15], demethylation of the same elements is not

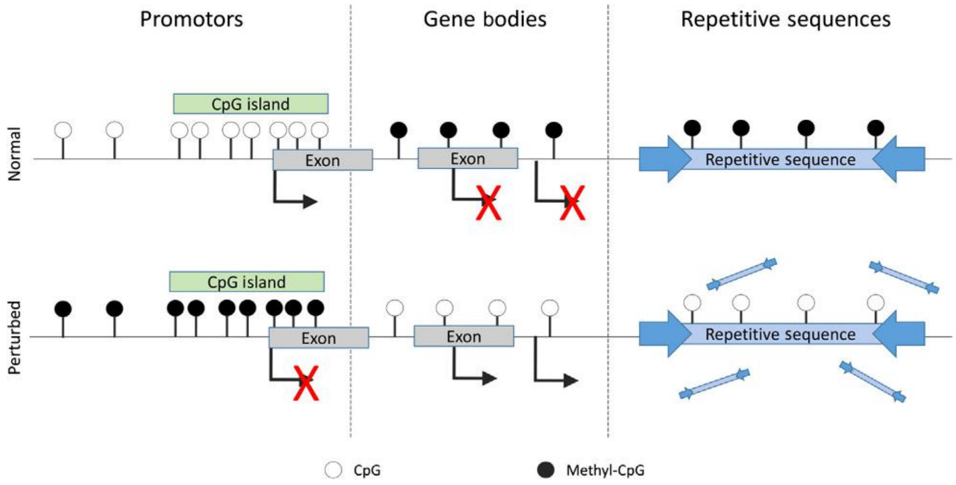

FIGURE 4.1 **DNA methylation can occur in different locations throughout the genome.** A variation from normal behavior is associated with disease. In the normal case, CpG islands are unmethylated while gene bodies and repeat regions tend to be methylated. This allows normal transcription originating from the transcription start site of the gene and transcription suppression elsewhere. In the perturbed case, CpG islands gain methylation while the gene body loses it. This inhibits transcription originating from the transcription start site while allowing spurious transcription in the gene body. Repeat regions also lose methylation; this has been linked to activation of repetitive elements, recombination, and genome instability.

always sufficient on its own to reactivate transcription [16]. Numerous cancers have been observed to have large-scale loss of methylation compared to matched normal control tissues [5,17,18], and it is thought that this hypomethylation may be responsible for reactivation of transposon elements, leading to decreased genome stability and the development of further genomic mutations in the tumor as shown in Figure 4.1.

Methylation has a well-documented effect on allele-specific expression. Normal development requires the contribution of both maternal and paternal genomes, but some genes are expressed only from the alleles of either the maternal or the paternal source. Artificially created genomes where both alleles have maternal (gynogenone) origins have double the expression of maternally derived genes and zero expression of paternally derived genes. The reverse is true of genomes with two paternal contributions (androgenones). These artificially generated genomes have been studied to determine that many allele-specific genes are involved in embryonic development.

One particular example of genomic imprinting is the IGF2r gene (insulin-like growth factor 2 receptor), which depends on the methylation of an intronic CpG island to control expression [19]. In the maternal copy of the gene, the promotor is unmethylated and active, which allows the production of the IGF2r mRNA, while an intronic CpG island is methylated. This intronic CpG island acts as a downstream promotor that is capable of producing an antisense RNA that can interfere with the gene's regular functioning. In the maternal copy of the gene, the intronic CpG island is inactivated by methylation. In the paternal copy of the gene, on the other hand, the intronic CpG island is unmethylated while the promotor is methylated. This allows the production of the antisense RNA via the downstream promotor coupled with transcription suppression from the coding strand via methylation of the gene promotor.

Several imprinted genes have been associated with cancers either as oncogenes (e.g., H19) or as tumor suppressors (e.g., CDKN1C). It is thought that, at least in some cases, methylation controls expression of imprinted genes via the modulation of enhancer access (via the CTCF protein) to the promotor [20]. In this model, CTCF suppresses expression of the IGF2 gene (insulin-like growth factor 2) via blocking of enhancer elements. This imprinting is then made allele-dependent by differential methylation patterns. Hence, DNA methylation controls gene expression by binding insulator proteins that can deny enhancer proteins access to the gene.

Another example of DNA methylation–linked silencing is chromosome imprinting (X-inactivation). In female mammalian genomes, one copy of chromosome X is largely inactivated by the formation of heterochromatin—although this does not affect every gene on the chromosome. Heterochromatin formation acts as a dosage compensation mechanism and ensures that the expression of genes located on chromosome X is roughly identical between males (one X chromosome) and females (two X chromosomes). Methylation is thought to promote the silencing of genes on the inactive X chromosome, although it occurs after gene repression and so may act to stabilize silencing. The inactive X chromosome is highly methylated at transcription start sites, but seemingly becomes hypomethylated across gene bodies and intergenic regions when it is inactivated [21]. Methylation therefore serves to imprint and reinforce an absence of transcription in the inactive X chromosome [22].

4.2.2 DNA Methyltransferases

Methylation is deposited and maintained by a family of catalytic enzymes known as DNA methyltransferases (DNA MTases, or DNMTs). These are categorized into two distinct classes: maintenance methylation and de novo methylation.

In normal somatic human cells, maintenance methylation occurs during every round of cell division. During DNA replication it is necessary to duplicate the original methylation patterns onto the newly synthesized daughter DNA strands. If maintenance methylation is interrupted or suppressed, the daughter strand of does not become methylated; this subsequently leads to passive demethylation. Maintenance methylation is primarily carried out by DNMT1. DNMT1 has a preference for hemimethylated CpG di-nucleotides (CpG di-nucleotides with discordant DNA methylation between the two strands), which are produced during replication [23] and relocated at replication foci. Mice that have heterozygous mutations (i.e., one working copy) in DNMT1 are indistinguishable from wild-type mice; however, homozygous mutants are embryonically lethal [24].

Unlike embryos, embryonic stem cells grown in culture with homozygous mutations are viable [24] with low but stable levels of methylation [25] that can be maintained for over 20 cell generations. This was one of the original pieces of evidence for the existence of methyltransferases which are independent of both DNMT1 activity and the cell cycle. DNMT3a and DNMT3b were identified through their protein sequence similarity to bacterial methyltransferases, and were shown to have equal catalytic activity on both unmethylated and hemimethylated CpGs [26], such that they are capable of de novo DNA methylation.

The DNMT3 family does not appear at replication foci [27], unlike DNMT1; instead, it is expressed throughout the cell cycle. The de novo methyltransferases are essential in establishing the methylation pattern of the organism and in de novo methylation during development [28] and embryogenesis [29]. Analysis indicates that DNMT1 may also have a role to play in methylation outside of replication. It is kinetically very slow in comparison to the DNA replication fork cycle [30], and it is difficult to see how it can keep up with the replication fork. DNMT1 has also been shown to be active during the G2 (cell growth and protein synthesis) and M (mitosis) phases of the cell [31], and activity outside of the S phase (DNA synthesis) is dependent on the TS (targeting sequence) domain in DNMT1 rather than on the PBD (PCNA-binding domain) that is used at the replication fork. Furthermore, DNMT1 interacts with the DNMT3 family [32], possibly as part of de novo methylation activity.

It is worth mentioning a protein previously classified as DNMT2 that has strong sequence similarity to the other methyltransferases and was once thought to be another DNA methyltransferase of unknown biological function. Ultimately, DNMT2 was found to methylate aspartic acid in transfer RNAs (tRNAs), thus protecting them against ribonuclease cleavage [33]. It was renamed TRDMT1 to reflect the change in understanding of its function.

A further modification that can be carried out on already methylated cytosine bases is the addition of a hydroxy group, which forms 5-hydroxymethylcytosine (5hmC). Hydroxy groups can be added by the oxidation of methylated cytosines by the Tet family of enzymes, and may be followed by decarboxylation in order to perform active cytosine demethylation [34]. Other functions of 5hmC are still unclear, although it is suspected to play a role in imprint erasure in germline cells [35], has been implicated in demethlyation of LINE-1 repeat elements [36], and is abundant in the brain [37], suggesting a role in regulation of neuron function.

4.2.3 Techniques for Measuring Methylation

There are a number of techniques for measuring DNA methylation levels—both for investigating specific sites or loci and for genome-wide approaches.

One cell-based approach is to stain the cells with an antibody that binds to 5-meC; this can be visualized using immunofluorescence or immunohistochemistry to obtain a gross overview of the abundance of methylation in the genome. Such an approach is frequently used to quantitate global levels of methylation in cells—for example, at different stages of development [38]—by observation of changes in the global level of methylation or changes in localization. However, because resolution is poor this technique can be used only to measure gross methylation levels.

5-meC antibodies can be further used to immunoprecipitate methylated DNA sequences (MeDIP). Genomic DNA is extracted from cells and sonicated into small fragments. It is incubated with 5meC antibodies and immunoprecipitation is used to remove unbound DNA. The remaining DNA is purified away from the antibody [39]. The quantity of DNA recovered from different loci can subsequently be measured by polymerase chain reaction for a single locus (MeDIP-PCR), by microarray for many preselected loci (MeDIP-chip), or by next-generation sequencing for a genome-wide view (MeDIP-seq). The resolution of MeDIP is limited by the size of the DNA fragments after sonication. Smaller fragments give greater resolution for PCR and array-based approaches, but they do not bind as efficiently with the 5meC antibodies (which bind better with multiple methylated sites) and pose targeting problems in designing unique primers (PCR) and probes (microarray). If fragments are very small, they can inhibit unique alignment of the sequenced fragment (NGS sequencing), which means that the resolution of MeDIP is practically limited to around 300 bp. The binding efficiency of the antibody, as well as the subsequent amount of DNA that is precipitated, is a function of both the methylation level of the fragments and the density of CpG di-nucleotides in them; thus, statistical tools are used to estimate the absolute methylation level by accounting for a region's CpG density [40].

A recent innovation is the use of affinity purification via the naturally occurring methyl-binding domain (MBD), extracted from the human MBD2 protein, which binds with symmetric meCpGs in double-stranded DNA. DNA is then captured through elution in steps, using a salt gradient that allows affinity-based capture [41] to achieve greater sensitivity than the comparable antibody-based approach along with greater yields. Importantly, the MBD approach utilizes a more flexible protocol and allows fractionation into low-, intermediate-, and high-CpG density fragments via variation of the elution buffer's salt content.

It is possible to obtain higher-resolution data on the distribution of methylation at individual CpGs through treatment of DNA with bisulphite ($NaHSO_3$), also known as sodium bisulfite. The addition of bisulphite to DNA triggers the conversion of cytosine to uracil, except where the cytosine is protected by a methyl group. The genomic loci of interest can then be amplified by PCR (which subsequently converts uracil to thymine) and subsequently directly sequenced [42]. Methylation-specific PCR, a recent development, removes the need to actually sequence the locus of interest [43] by designing complementary pairs of PCR primers that are methylation-specific and unmethylation-specific and are used in parallel. Methylation level is determined by the respective ability of the primers to anneal specifically to the region of interest and therefore their ability to amplify the DNA region under examination.

Microarrays were developed as an extension of the techniques just described. DNA is bisulphite-converted and hybridized to a microarray that contains between hundreds and hundreds of thousands of probes for individual CpG di-nucleotides. Each probe consists of a pair of oligonucleotides specific to the CpG targeted; one probe contains a CGN sequence and the other contains a TGN sequence, so representing methylated and unmethylated CpG status respectively [44]. The level of methylation for a given probe can then be calculated by the ratio of florescence between the two oligos. Modern arrays range from 27,000 to 450,000 probes [45].

With the development of next-generation sequencing (NGS) technology, it has become possible to directly sequence the bisulphite-converted DNA fragments at high coverage. Genome-wide bisulphite sequencing allows quantitation of virtually all CpG di-nucleotides in the genome as well as examination of cytosines in non-CpG contexts. This has allowed the examination of large domains of methylation [46], which previously had not been readily accessible to approaches forced to target focal regions of interest—typically, CpG islands and genic regions.

As NGS is extremely expensive, it is still necessary to consider more cost-effective approaches to collecting methylation data for the whole genome. Reduced-representation bisulphite sequencing (RRBS) is one such approach that first uses a restriction enzyme (Mspl) to cut genomic DNA at CCGG sites [47]. Size-selecting the resulting fragments to the 40–220 bp range results in selection toward most CpG islands in the genome. It is then possible to bisulphite-treat this DNA as normal and sequence it using NGS technology to obtain high-coverage, single-base-pair-resolution methylation data for most of those CpG islands. Similarly, it is possible to specifically target one or more extended genomic regions of interest by using targeted enrichment approaches [48] to enrich specific regions of DNA—for example, by using a library of thousands or millions of baits to hybridize to and select for targeted DNA sequences. Bisulphite sequencing cannot differentiate between 5mC and 5hmC because both types prevent the conversion of cytosine to uracil. One modification for differentiating the two is two-step oxidative bisulphite sequencing (OxBS-seq) [49]. Oxidation of 5hmC to 5fC (5-formylcytosine) is first achieved via potassium perruthenate, which does not modify either unmethylated or 5mC methylated cytosines. Bisulphite treatment is then carried out to convert both unmethylated and 5fC cytosines into uracil, and in this way the OxBS-seq can specifically record only 5mC methylation. By performing traditional and oxidative bisulphite sequencing in parallel, it is possible to subtract the 5mC-specific readout from the total methylated bisulphite signal to determine 5hmC distribution.

Another modified approach is Tet-assisted bisulphite sequencing (TAB-seq), which uses the enzyme TET1 to convert 5mC into 5caC (5-carboxylcytosine) [50]. First a glucose is added to 5hmC using β-glucosyltransferase (βGT) to form 5gmC (β-glucosyl-5-hydroxymethylcytosine). This protects the existing 5hmC from TET-mediated oxidation. After all existing 5hmC is blocked, all 5mC is converted to 5caC using the TET1 protein. Bisulphite treatment of the resulting DNA converts all unmethylated cytosines to uracil and all 5caC (originally 5mC) to 5caU, while the blocked 5hmC remains protected as 5gmC. Sequencing results in a cytosine base originally 5hmC and a thymine base originally unmethylated or 5mC-methylated. This provides specificity in determining the levels of 5hmC by excluding 5mC methylation.

4.3 HISTONES AND VARIANTS

A nucleosome is the basic structural unit in which DNA is packaged. A single DNA base pair is approximately 0.34 nm long [51]. The human genome contains 6 billion such bases (3 billion–base diploid genome), which is approximately 2.04 m DNA per cell. Histones are highly conserved basic proteins that form a nucleosome by wrapping 147 base pairs

TABLE 4.1 Known Human Histone Variants Obtained from the UniProtKB Protein Database

Histone Family	Variants
H1	H1.0, H1oo, H1x, H1.1, H1.2, H1.3, H1.4, H1.5, H1t
H2A	Macro-H2A.1, macro-H2A.2, H2A.J, H2A.V, H2A.x, H2A.Z, H2A type 1 (A,B/E,C,D,H,J), H2A-Bbd type 1, H2A type 2 (A,B,C), H2A-Bbd type 2/3, H2A type 3
H2B	H2B type 1 (A,B,C/E/F/G/I,D,H,J,K,L,M,N,O), H2B type 2 (C,D,E,F), H2B type 3-B, H2B type F (M,S), H2B type W-T
H3	H3-like centromeric protein A, H3.1, H3.1t, H3.2, H3.3, H3.3C
H4	No known sequence variants

of DNA around two copies of each of the four core histones (H2A, H2B, H3, and H4) in an octamer. The very basic nature of histones allows a tight binding with the acidic DNA to form a characteristic "beads on a string" structure.

The H1 linker histone does not form part of the core nucleosome, but instead can bind at the nucleosome's DNA entry/exit point to lock the DNA into place and, it is thought, to allow nucleosomes to be pulled together to form higher-order structures. Unlike the four core histones, there is only one copy of the H1 linker histone per nucleosome.

The combination of nuclear DNA, RNA, and proteins (including histones) is referred to as the chromatin. Open chromatin, or euchromatin, refers to chromatin considered to be easily accessible, lightly packed, and often transcribed in interphase cells. In contrast, closed chromatin, or heterochromatin, remains condensed in interphase and is thought of as tightly packed to prevent transcriptional activity. Heterochromatin is often subdivided into constitutive heterochromatin, located at highly repetitive regions (e.g., pericentromeres and telomeres) and always present, and facultative heterochromatin, which can be located anywhere in the genome and often performs a regulated gene-silencing function (e.g., the inactive C chromosome [52]).

While histones are among the slowest-evolving proteins, there are some variants that result in sequence differences. Examples of these variants are listed in Table 4.1. Histone variant names are based on UniProtKB protein names. Several histone variants have multiple subtypes, which are indicated in parentheses and separated by commas in the table. Some subtype names include a forward slash, indicating that the variant is transcribed from multiple genes but has the same amino acid sequence. Histone variants, in general, may be transcribed from multiple genes (data not listed) but generate the same amino acid sequence.

The chromatin structure can be modified by different histone variants to create different chromatin environments in localized portions of the genome, and sometimes in a tissue-specific fashion (e.g., testes variants). This allows chromatin to regulate a number of DNA functions such as gene expression and DNA damage [53].

Histone H1 has a number of variants that range from 21–29 kDa (194–255 amino acids). Its variants are often classified by the strength of their linker function into strong (H1.0, H1.4, H1.5, H1x), intermediate (H1.3), and weak (H1.1, H1.2) based on their ability to condense the chromatin [54]. Histone H1 can be further categorized by tissue origin; H1.2 and H1.4 are found in most somatic cell nuclei while some H1 variants (H1t, H1oo) are germline-specific and regulate chromatin structure during spermatogenesis and fertilization [55,56].

Histone H2A has the largest number of variants, most of which are approximately 14 kDa (~130 amino acids) although some vary considerably in size. Some H2A variants appear to have been highly conserved through evolution (i.e., H2A.Z) and have been associated with active or potentially active chromatin [57], particularly around the transcription start site of active genes [58]. The macroH2A variant are much larger version of H2A at around ~40 kDa (327 amino acids). They mark repressed chromatin in a signal-dependent fashion [59] and is enriched on the inactive X chromosome [60], where it is thought to suppress transcription in part through inhibition of PARP-1 [61]. In contrast, the H2A Barr body-deficient (H2A-Bbd) variant wraps only 118 base pairs of DNA and is found only on the active X chromosome [62], where it is associated with transcriptionally active regions of the genome.

Histone H2B is another 14 kDa protein, consisting of approximately 126 amino acids and having several variants, although their roles are not well understood. One of the few variants with a known function is H2B W-T, a testes-specific variant; nucleosomes containing it have been shown, unlike conventional H2B, to be unable to recruit chromosome condensation factors [63].

Histone H3 is 15–16 kDa protein (~135 amino acids). Its three main forms are H3.1, H3.2, and H3.3. H3.1 and H3.2 differ by only one amino acid, although they may serve different roles. H3.1 has been shown to be localized to regions that can be switched to active or repressed based on the state of the cell, while H3.2 is thought to be enriched in transcriptionally repressive domains [64,65]. In contrast, H3.3 is often associated with transcriptionally active chromatin and active and poised gene promoters and regulatory elements, and is thought to replace existing H3

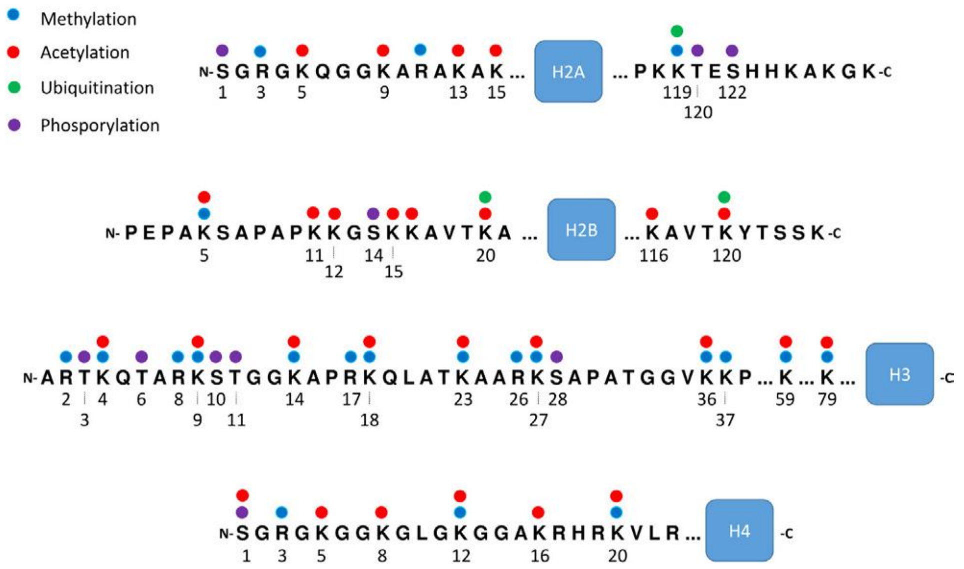

FIGURE 4.2 **Histone modifications are prevelant on the histone tails.** Shown is a representative sample of the most commonly studied histone modifications (methylation, acetylation, ubiquitination, and phosphorylation) for the four core histones. Modifications can also affect the globular region of the histone (not shown). Numbers indicate amino acid position in the histone sequence.

histones during transcription [66]. H3.3 is also recruited to telomeres during telomere replication and processing [67] in stem cells. CENPA is a 17 kDa H3-related protein that drives the assembly of centromeres [68].

H4 is 11.3 kDa (102 amino acids) and is the most conserved histone; it has no described human sequence variants [69]. This is possibly because it has docking sites for all three of the other core histones [70] and any significant variation may compromise the structure or stability of the nucleosome.

The bulk histone content in a cell is duplicated when the cell passes through the S phase (DNA synthesis phase) of the cell cycle. This relatively short phase results in an extremely high demand for histones to create the chromatin on the newly synthesized DNA. Histone transcripts created during S phase are termed replication-dependent and are characterized by their lack of introns and polyadenylated 3′ end; instead, they have a purine-rich sequence forming a stem-loop structure [71]. SLBP (stem-loop–binding protein) binds to this sequence and facilitates mRNA stability, nuclear export, and translation in proliferating cells [72]. In contrast, replication-independent histones (such as H1.0 and H3.3) are transcribed throughout the life of the cell and feature a poly(A) tail to facilitate canonical mRNA metabolism via poly(A)-binding proteins (PABPs).

Histones can be added and removed from DNA by chaperone complexes that allow the histones in each nucleosome to be changed according to gene expression programs. Examples of histone chaperones include HIRA (replication-independent) and DAXX (replication-dependent), which are both responsible for deposition of histone H3.3 to DNA.

4.3.1 Histone PTMs

In addition to the numerous histone variants, there are a multitude of post-translational modifications (PTM) that can change the behavior and functionality of the histone-containing nucleosome. Each of the core histones contains an N-terminal tail protruding from the nucleosome on which most of these modifications take place. Amino acids in the tails can be subjected to many covalent modifications, including methylation (mono-, di-, tri-), acetylation, phosphorylation, and ubiquitination. Other modifications include sumoylation, citrullination, and biotinylation. Modification of the histone tail can manipulate chromatin formation directly or may allow or disallow the binding of different transcription factors. Some modifications are mutually exclusive (i.e., they occur at the same amino acid), while others may be combinatorial [73], occurring simultaneously on different residues to regulate chromatin function. A summary of commonly studied histone post-translational modifications is provided in Figure 4.2.

Post-translational modifications are identified by a standard nomenclature indicating (1) name of the core histone; (2) amino acid affected using the IUPAC single-letter codes (e.g., K for lysine, R for arginine); (3) amino acid position in the protein (starting from the N-terminus); (4) type of modification (me: methyl, ph: phosphate, ac: acetyl, ub: ubiquitin); and, optionally, (5) number of modifications (one, two, or three). For example, H3K4me3 indicates tri-methylation of Lysine 4 on histone H3.

Histone modifications are carried out by families of enzymes, such as histone methyltransferases (HMT) or acetyltransferase (HAT). Similarly, they can be reversed by histone demethyltransferases (HDMT) or Deacetylase (HDAC) enzymes.

4.3.2 Histone PTM Effects

There are many potential consequences of post-translational modification of histones. Trimethylation of lysine 4 on histone H3 is associated with activated transcription when located near the transcription start site to activate genes [74]. H3K36me3 in the gene body similarly indicates actively transcribed genes. However, methylation of lysines 9 and 27 typically correlates with transcriptional repression [75].

Histone acetylation removes the positive charge, which relaxes the interaction with negatively charged DNA and is thought to make it more euchromatic and accessible to transcription [76,77], DNA repair [78], and histone deposition [79]. Post-translational modifications have been associated with numerous other biological functions and contexts, including polycomb-mediated prevention of transcription elongation during spermatogenesis [80], apoptosis [81], and mitosis [82].

Each histone can be covalently modified, and each can be modified on multiple amino acids. Several amino acids support multiple types of modification, which has raised the notion of a parallel histone code or histone language [83] that is perhaps as important as the DNA code. The combinatorial effects of histones are significant. One such effect is the ability of histone modifications to cooperate and reinforce each other. For example, inactive regions/heterochromatin are marked by low levels of acetylation, low levels of activating marks (H3K4me, H3K36), and high levels of inactivating marks (H3K9me, H3K27me) while in active regions/euchromatin this trend is reversed [73,84].

In addition to individual effects of single modifications or the cumulative effect of modifications with similar functions, combinations of histone modifications can encode more dynamic behavior. One typical example is bivalent domains [85] found in embryonic stem cells where genes are simultaneously marked with both repressive (H3K27me3) and activating (H3K4me) histone modifications. The repressive mark takes precedence over the activating mark. However, the gene is kept poised and can be activated by simple removal of the repressive mark. This may allow more rapid activation of the gene than would be possible with the sequential removal of H3K27me and the subsequent addition of H3K4me.

Similarly, histone modifications may interact with each other even where they do not share the same amino acid. H3K36me3, while associated with active transcription, is known to recruit a HDAC complex [86] that prevents the acetylation of histones and the subsequent initiation of transcription in the gene body.

4.3.3 Techniques for Measuring Histones and Other Chromatin-Interacting Proteins

A frequently used approach for measuring protein interaction with DNA is chromatin immunoprecipitation (ChIP) [87]. DNA is first cross-linked to form a covalent bond between physically nearby proteins and DNA (i.e., both protein–DNA and protein–protein bonds). As in MeDIP, an antibody is used to precipitate the protein of interest and the DNA fragments associated with the protein are then purified. ChIP can be combined with PCR (ChIP-PCR) to probe a specific region of interest; it can be used with a tiling array (ChIP-chip); or it can be combined with NGS technologies to determine genome wide protein–DNA binding (ChIP-seq). Like MeDIP, the resolution of ChIP is limited to a few hundred base pairs; however, it is possible to use exonucleases to degrade exposed DNA before sequencing to improve resolution [88], although this comes at the cost of shorter reads from the DNA sequencer that are subsequently more difficult to uniquely map to the genome.

One difficulty with ChIP is that it relies on the availability of specific and sensitive antibodies to each protein of interest, whereas MeDIP relies only on a single well-characterized antibody. In the case of histone variants, or post-translational modifications, specific antibodies may not be readily available because of the small differences between variants and PTMs. Thus, antibodies may not be able to specifically recognize a given histone variant/PTM or may recognize multiple variants/PTMs. It is therefore vitally important that ChIP studies for histones employ extensive validation and screening for antibodies, using peptide arrays to check for antibody specificity and sensitivity.

An alternative to the ChIP procedure is labeling the DNA close to the binding site of the protein of interest. DamID [89] involves the creation of a fusion protein composed of Dam (DNA adenine methyltransferase), which has been extracted from E-coli and methylates adenine, and a DNA-binding protein (i.e., the protein of interest). Expression of this fusion protein leads to the methylation of adenine in GATC sequences near the protein's binding site without any other noticeable effects. Methylated adenine is absent in eukaryotes, so any methylation of GATC sequences is likely due to the proximal binding of the protein of interest. DNA is then digested with the DpnI enzyme, which cuts only methylated GATC sites. The sequence at the ends of the DNA fragments is known, so adapters can be ligated to the ends resulting from digestion and so PCR with matching primers can be carried out. The result is that fragments flanked by the methylated GATC sites are amplified.

Alternatively, a methylated adenine-specific antibody can be used, as in MeDIP. The Dam protein itself has intrinsic DNA-binding activity, so it is necessary to compare the Dam–protein fusion to a Dam-only negative control to filter out "background" adenine methylation as a result of Dam binding. DamID can be combined with microarray technologies (DamID-chip) [90] or with NGS technologies now available [91].

A modification of the bisulphite-sequencing approach can measure nucleosome occupancy simultaneously with assessment of DNA methylation (NOMe-Seq). Briefly, this involves the addition of a GpC methyltransferase (M.CviPI), and it relies on differences in methyltransferase accessibility to GpC sites in isolated chromatin. Because the majority of GpC sites are physiologically unmethylated (only possible in a GpCpG context), it is inferred that, upon sequencing, any GpC sites that are methylated are the result of exogenous M.CviPI. If a GpC site is unmethylated, it is further inferred that this is because of the enzyme's inaccessibility and the site is subsequently used as a readout of nucleosome occupancy [92]. Simultaneously, *in vivo* methylation status can be read from the unaltered CpG sites and, importantly, can be retrieved from the same molecule—allowing a direct comparison of methylation and nucleosome occupancy in a single cell. Unfortunately, mC in a GpCpG context is difficult to interpret by this method.

One final approach is the combination of ChIP with bisulphite sequencing. The DNA fragments that are obtained from ChIP can be bisulphite-treated such that the methylation status of the protein's binding domain can be examined—a process referred to as ChIP-BS [93]. ChIP-BS allows examination of methylation in the context of specific transcription factors and/or histone modifications—for example, to determine if methylation status and a particular chromatin-binding protein are related.

4.4 EPIGENETIC DISORDERS AND THERAPIES

There are a number of imprinting-related disorders that occur either from heterozygous loss of an imprinted gene or from loss of imprinting. Chromosome 15 q11–13 is associated with the development of Prader-Willi syndrome (PWS) and Angelman syndrome (AS) [94]. This region contains genes that are expressed only from maternal or paternal contributions. Mutation, deletion, or loss of function of a single gene (UBE3A), which is expressed exclusively from the maternal allele, is sufficient to cause AS despite the presence of an intact but unexpressed copy on the paternal allele. Loss of paternal contribution of this region leads to PWS, although the specific genes involved are less well established—many genes in the region are expressed only from the paternal contribution, but none have been linked definitively to the condition. The most likely candidate is a snoRNA gene cluster [95,96], but this does not seem sufficient on its own to cause the disorder [97]. PWS may therefore be the result of the combinatorial loss of imprinted genes in the snoRNA cluster and other, as yet unknown gene abnormalities.

In addition to imprinting disorders caused by loss of an individual parental genetic contribution, loss of imprinting itself can be due to the disruption of epigenetic marks (gain or loss of methylation). The IGF2/H19 locus is well studied in terms of imprinting disorders and is known to be deregulated in cancers [98] and in other disorders such as Beckwith-Wiedemann syndrome [99]. The protein CTCF is involved in regulating expression of this gene. It is sensitive to methylation status at its binding site [100] and acts as a chromatin insulator that divides the genome into functional domains; it also regulates the ability of enhancers and transcription factors to access promotors and prevents increases in methylation [101]. Loss of imprinting at the IGF2/H19 locus is associated with loss of CTCF because of methylation changes, without any apparent mutations of CTCF or its binding site [102].

Many cancers have large domains of DNA hypomethylation [18,103,104] along with more focal areas of hypermethylation [5,17,105]. Hypomethylation is an early event [106] and increases with disease stage [16], suggesting that it has roles in both cancer initiation and maintenance. Hypermethylation of CpG islands is thought to play a role in repressing tumor suppressor genes—silencing of these genes provides a growth advantage for the affected population of cells and increases their survivability [107]. Treatment with 5-azacytidine and 5-aza-2′-deoxycytidine, which block maintenance methylation during replication, has been proposed as cancer therapy [108,109] to inhibit CpG island hypermethylation; both are approved for use in humans in several countries for cancers such as AML and MDS in several countries.

Huntington's disease is caused by a mutant huntingtin gene (Htt) that in normal cases has a CAG (glutamine) repeated fewer than 26 times. Huntington's disease is caused by the extension of this repeat in at least one allele of the gene to a sequence of greater than 36 repeats, resulting in a protein that causes an increased decay rate of neurons [110]. One hypothesis is that mutant huntingtin binds to CBP and/or P/CAF and reduces their availability to mediate histone acetylation at genes that promote neuronal survival. Treatment with HDAC inhibitors (to compensate for loss of CBP and/or P/CAF function) has been shown to help in drosophilia [111] and mouse [112] models of Huntington's. HDAC inhibitors are also considered a suitable approach for restoration of learning and memory in neurodegenerative diseases [113] and as anti-cancer therapies [114], although their method of action is still not completely known. HDAC inhibitors have also been approved for human use in some locations.

Histone variants and modifications have been linked to aging. Specifically, H4K16 acetylation's regulation of cellular lifespan [115] is known to be through interaction with Sir2. Sirtuins, including Sir2, are a family of conserved deacetylases with connections to longevity and/or healthspan in a number of species. In yeast, Sir2 deacetylates H4K16ac; an age-associated decrease in expression of Sir2 correlates with an increase in H4K16ac and impaired transcriptional silencing. Suppressing H4K16ac levels via deletion of an acetyltransferase (Sas2) increases cell lifespan. Mutations in H4K16 and H3K56 have been shown to result in reduced lifespan [115]. Furthermore, methylation of histone 3 is known to affect the lifespan of worms via H3K4me3 in the germline [116] and in somatic cells via H3K27me3 [117].

Histone modifications have been further implicated in cancer, and there is evidence that cancers can be promoted by abnormalities in histone methylation. Global loss of H4K9me3 has been observed in multiple cancer lines [118], while hypermethylation of H3K9 and hypomethylation of H3K4 are characteristic of transcriptionally silenced heterochromatin in cancers. Histone demethylase (HDM) activity has been further linked to neurological disorders and cancer [119].

There is evidence that the level of H3K27 methylation is important for normal cell growth and that deregulation of this modification is associated with multiple cancers. H3K27 methylation is catalyzed by EZH2—the histone methyltransferase that modifies H3K27—and mutations or disregulation of this gene are found in multiple cancers [120,121]. High EZH2 expression is prognostic of poor patient progression and for this reason EZH2 inhibitors are an active area of research [122].

4.5 CONCLUSION

This chapter summarized the mechanisms and effects of DNA methylation, histone variants, and histone modifications. Tools for measuring and manipulating each of these epigenetic marks were presented. A brief summary of the role of epigenetic marks in diseases such as cancer was also provided.

While methylation and histone variants/modifications have individual effects, they have also been shown to interact at a molecular level, so it is important to consider possible combinatorial effects. DNA and histone methylation have been shown to cooperate, and DNA methylation is essential to ensure that histone methylation (H3K9me) is maintained through DNA replication, mediated by the Methyl-CpG–binding protein (MBD1) [123]. H3K9me is required for DNA methylation in neurospora crassa [124] and arabidopsis thaliana [125].

The study of epigenetics is important for understanding cell function, differentiation, and behavior in disease. Because so many diseases involve changes to methylation and/or histone variants and modifications, it is important to understand the effect they have so that they can be reversed with clinical treatments or used as biomarkers for diseased cells. As these changes are reversible (unlike DNA mutations), the process of manipulating them should be more feasible through drug-based treatments.

Chapter 5

Animal Models in Pharmacogenomics

Erin Olson and Delyth Graham

BHF Glasgow Cardiovascular Research Centre, University of Glasgow, UK

Chapter Outline

5.1 Overview 73
5.2 Rodent Models 74
  5.2.1 Mouse Models 74
  5.2.2 Rat Models 74
  5.2.3 Outbred Rodent Stocks 74
  5.2.4 Inbred Strains 75
  5.2.5 Heterogeneous Stocks 75
  5.2.6 Collaborative Cross 75
  5.2.7 Recombinant Inbred Strains 76
  5.2.8 Congenic Strains 76
  5.2.9 Consomic Strains 77
  5.2.10 Transgenic Rodent Models 77
5.3 Nonrodent Models of Human Disease 79
5.4 Genetic/Genomic Resources 79
5.5 Ethical Issues of Animal Experimentation 80
  5.5.1 Replacement 80
  5.5.2 Refinement 80
  5.5.3 Reduction 80
5.6 Caution and Limitations 80
5.7 Applications of *in vivo* Models in Pharmacogenomic Research 81
  5.7.1 Quantitative Trait Mapping 81
  5.7.2 Identification of eQTLs 81
5.8 Rodent Models in Pharmacogenomics 82
  5.8.1 Bipolar Disorders 82
  5.8.2 Anxiety Disorders 82
  5.8.3 Pharmacogenomics Using Xenograft Mouse Models of Acute Leukemia 82
  5.8.4 Pharmacogenomics of Pain and Analgesia 83
  5.8.5 Pharmacogenomics and PAH 84
  5.8.6 Pharmacodynamic/Pharmacogenomic Modeling of Insulin Resistance 84
5.9 Conclusion 85
References 85

5.1 OVERVIEW

Pharmacogenomics is the application of genome-wide approaches for determining genetic influences on drug response and for the development of novel therapies. By investigating the gene expression profile of an individual disorder, specific therapy can be targeted to that disorder, leading to greater efficacy and reduced toxicity [1]. Recent advances in high-throughput methods of generating biological datasets and in the computational power and bioinformatics needed to manipulate these vast datasets have completely transformed the manner in which this research is conducted. Where human studies are ethically or practically impossible, animal models can play an important role in pharmacogenomic investigations.

This chapter discusses the approaches available to exploit high-throughput technology and the genetic diversity of rat and mouse species in mechanistic pharmacogenomics research. It also provides evidence to show that the use of appropriate genetically defined rodent models not only aids identification of genetic determinants of drug susceptibility but also helps to establish underlying mechanisms.

Human pharmacogenomic studies can be particularly problematic in terms of tissue collection and intervention. Generally, it is not possible to obtain tissues from a wide variety of anatomical sites or during different developmental stages in humans. Additionally, it is ethically unacceptable to expose humans to toxic substances or carry out genetic engineering. While cell-based assays can provide a useful

alternative for generating pharmacogenomic datasets and have been used extensively in preclinical drug development, *in vitro* studies examine pharmacology in isolation from adaptive and regulatory networks and signals that exist in the whole organism [2]. Thus a great importance is attributed to experimental animal models. Currently the most utilized models are the mouse and the rat.

5.2 RODENT MODELS

Genetic studies using rodents can circumvent many of the limitations commonly encountered with human studies and *in vitro* approaches in pharmacogenomics. Inbred rodent models allow studies to be conducted on a homogeneous genetic background, thereby reducing the noise generated from human heterogeneity. Moreover, in rodent studies gene–environment interactions are minimized, well-defined, and well-controlled when compared to human studies [3]. The traditional role of rat and mouse models has been further supported by the sequencing of their genomes, where rodent models have been shown to have greater evolutionary relatedness to humans than expected [4].

Rats are commonly used in drug-safety evaluation experiments, and genetically diversified inbred strains are being developed and used for population-based toxicity testing [5]. However, the most widely used laboratory model for pharmacogenomic studies is the mouse, which, until very recently, offered an unparalleled wealth of genetic knowledge and resources, including a high-density SNP database containing more than 8 million polymorphic loci in hundreds of inbred strains [6–8].

5.2.1 Mouse Models

There are many advantages to using mice as research models: specifically, their genetic characterization, the large number of strains available, and the large list of cataloged mutant genes that provide models suited to a number of different areas of research. Mice are relatively inexpensive to breed and maintain compared to other species. They are also easy to handle and care for. Their high reproductive performance, large litter size, and short gestation means that many generations can be produced in a relatively short period of time (with the potential for 1 million descendants after 425 days).

The disadvantages of mice as research animals include their small size, which can limit the procedures that may be performed, and the sample volume size that can be obtained from an individual animal. In order to overcome volume size limitations, samples from several animals may be pooled for research analysis and for improved statistical power.

The use of the mouse as a research animal has resulted in many scientific advances. Much of our early understanding of the immune system resulted from mouse studies [9]. The use of the mouse continues to be an important part of various fields of research, including embryology, aging, cancer, pharmacological and toxicological testing, and infectious disease. Transgenic and knockout mice have become important tools for investigating the relationship of genetic makeup to disease states as well as for elucidating pathways of normal mammalian development [10].

5.2.2 Rat Models

The laboratory rat was the first mammalian species domesticated for scientific research, and it has been a well-studied animal model across the biomedical sciences. Inbred rat strains were first established by Helen Dean King nearly a century ago [11], and they are used for research into a broad array of human conditions and diseases, such as addiction, aging, autoimmunity, cardiovascular disease, hypertension, metabolic disorders, and cancer. Because of its well-studied physiology and the relative ease of experimental intervention, the rat is also widely used in the pharmaceutical industry to assess the efficacy and toxicity of drugs.

While the rat has been primarily known as an excellent "physiological" model, it has lagged behind the mouse as a genetic model in the endeavor to identify genetic contributions to disease. In recent years, however, there has been a steady increase in the use of the rat for genomic and genetic studies [12,13]. The use of the rat for genetic/genomic research was transformed by the sequencing of the rat genome in 2004 [4], which provided an exceptional opportunity for identifying genes and pathways underlying disease phenotypes. In evolutionary terms, the rat is approximately 5 million years closer to the human than the mouse, thus allowing greater translational opportunities [14].

There are three main genetic types of rodent used in biomedical research. These are (1) animals that come from a genetically heterogeneous (nonisogenic) group, such as an outbred stock, an F_2 hybrid, or a genetically heterogeneous colony, (2) animals that come from a genetically uniform (isogenic) group, including inbred strains and F_1 hybrids; and (3) animals expressing a major gene mutation.

5.2.3 Outbred Rodent Stocks

Outbred rodent stocks (e.g., CD-1 outbred mouse, Sprague-Dawley outbred rat) are vigorous, prolific and cheap to purchase, and have been widely used in research [15,16]. They are usually maintained as large breeding colonies within which there is inter-individual genetic variation. They are maintained by random (or haphazard) mating systems. Each animal will be genetically different, but the extent of genetic variation depends on the parental strain origins of the colony. For example, when a new colony is established or during caesarean rederivation for the elimination of disease, genetic variation will be reduced whereas an outcross to a different stock will increase variability.

As research models, outbred stocks have a number of disadvantages. For one, their characteristics can change rapidly due to selection, inbreeding, and random genetic drift. Also, outbred animals are usually significantly heavier than inbred ones as a result of many generations of selection for fast growth rate and large litter sizes. They are additionally "genetically undefined"—that is, the genotype of an individual is unknown unless it is specifically assessed. Stock names such as "Sprague-Dawley," "Wistar," or "Swiss" have little genetic meaning, and there are no genetic markers to define them. Outbred stock from different breeders will be genetically different (due to different husbandry regimes), which means that historical data collected on such stocks may be unreliable, making quality control difficult.

The use of outbred stock is often justified on the grounds that "humans are outbred," which should make it easier to "extrapolate" to humans [16]. However, except for certain specialized uses (e.g., heterogenous stock for sub-centimorgan fine mapping of quantitative trait loci or the Collaborative Cross, a resource for mammalian systems genetics), outbred stocks are not the most suitable model for genetic research. Their use leads to a larger number of false negative results because phenotype variability inevitably leads to lower-powered experiments. The almost universal use of outbred stocks in toxicity testing has arisen by historical accident and has not been scientifically justified.

5.2.4 Inbred Strains

Inbred strains are produced by greater than 20 generations of brother × sister mating, with all individuals tracing back to a single pair in the twentieth or subsequent generations [17]. They are genetically stable and cannot be changed by selective breeding. However, sublines have arisen in most of the commonly used strains as a result of residual heterozygosity (i.e., the sublines were separated before the strain was fully inbred) and new mutations, which can result in genetic drift within geographically isolated sublines of the same inbred strain. There are more than 400 inbred strains of mice and 150 inbred strains of rats, and geneticists have recognized their value for many years.

The key characteristics of inbred strains are as follows:

- Isogenicity: all individuals within a strain are genetically identical, so the same genotype can be repeatedly reproduced.
- Homozygosity: animals are homozygous at virtually all genetic loci. This leads to immortality of the genotype because offspring are genetically identical to their parents.
- Phenotypic consistency: uniformity of the phenotype means greater statistical power and the requirement for fewer animals per experimental group.
- Long-term stability: once fully inbred, these strains are not changed by selective breeding. New mutations will lead to gradual genetic drift, so it is important for investigators to specify the substrains they use.
- Identifiability: each inbred strain has a unique set of genetic markers that can be used for genetic quality control, allowing regular marker screening to ensure maintenance of homozygosity within the colony.
- Individuality. each strain is unique and has particular phenotypic characteristics that are important for addressing specific research questions. Studies using particular inbred strains of mice (e.g., C57BL/6) or rats (e.g., Dahl SS) are well-accepted research strategies provided it is clearly understood that the results may apply only to that strain and may not be relevant to other strains.

Inbred strains represent fixed, renewable genotypes that are ideally suited to systems biology approaches and to identification of whole-genome response signatures.

5.2.5 Heterogeneous Stocks

Both rat and mouse heterogeneous stocks (HS) have been generated as alternative models for fine mapping of small-effect quantitative trait loci (QTLs) [18–20]. These genetically heterogeneous rodent models are outbred animals of known ancestry, descended from eight inbred progenitor strains, and outcrossed to maintain diversity. The stock is maintained for more than 50 generations so that each chromosome is a fine-grained mosaic of the progenitor strains. The average distance between recombinants is small (less than 2 centimorgans) so that the HS are a powerful tool for high-resolution mapping of multiple QTLs across the genome.

5.2.6 Collaborative Cross

The collaborative cross (CC) is a large panel of mouse recombinant-inbred (RI) strains derived from a genetically diverse set of founder strains and designed specifically for complex trait analysis [21–24]. The CC is characterized by genome-wide genetic variation, randomization, and a reproducible stable population that is sufficiently large to support statistical analysis. The eight founder strains (A/J, C57BL/6J, 129S1/SvImJ, NOD/LtJ, NZO/HlLtJ, CAST/EiJ, PWK/PhJ, and WSB/EiJ) were bred through an eight-way "funnel" breeding design established to randomly mix the variation in the founder strains before inbreeding by brother × sister mating (Figure 5.1). The founder strains were chosen in order to maximize genetic diversity and utility for studying traits of widespread interest. The eight collaborative cross-founders capture ~90% of allele diversity across all 1 Mb intervals spanning the mouse genome. This is compared to the most commonly used RI mouse strains

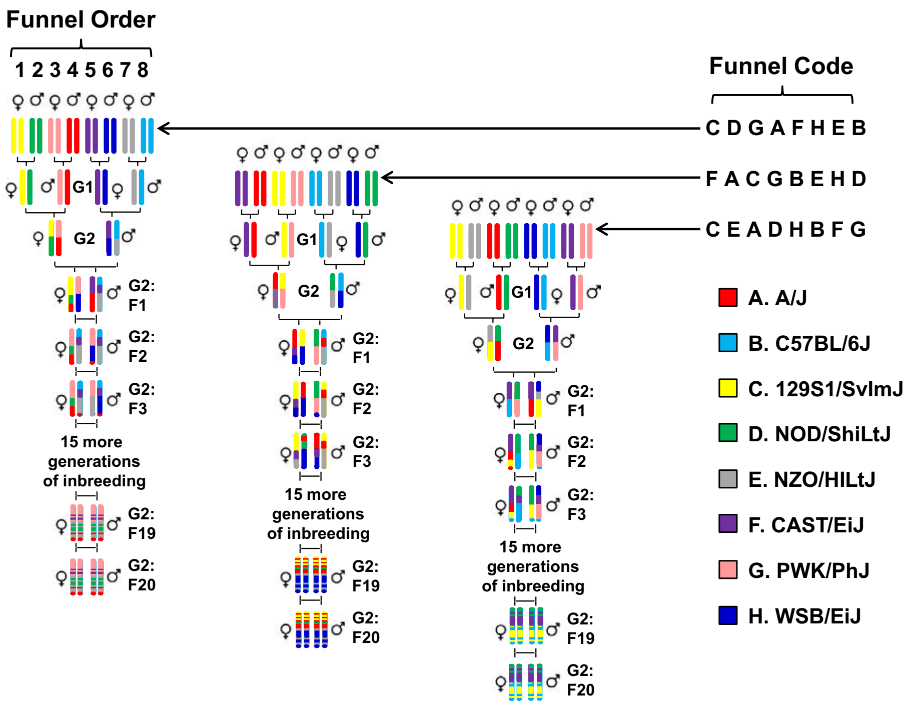

FIGURE 5.1 **Breeding scheme of CC lines.** The figure shows the breeding scheme for three independent CC lines. Each line has a funnel section followed by an inbreeding section. The eight founder strains are arranged in different positions (1–8) in each line, and this order determines the funnel code on the basis of a single letter code for each line. Founder order is randomized and not repeated across lines. Each mouse is represented by a pair of homologous autosomes and a symbol denoting its sex. *Source: Adapted from the Collaborative Cross Consortium* [24].

(AXB/BXA and BXD), which each capture only approximately 13% of known variation. The CC has a population structure that randomizes existing genetic variation, providing unparalleled power to determine causality and investigate detailed biological networks underlying disease and drug response [24].

5.2.7 Recombinant Inbred Strains

Rat and mouse recombinant-inbred strains (RIS) provide powerful tools for genetic mapping [25,26]. An RIS is formed by crossing two inbred strains followed by repeated (>20 generations) brother × sister mating to create a new inbred line whose genome is a mosaic of the parental genomes (Figure 5.2). Since each RIS is an inbred strain, it can be generated perpetually. A panel of RIS has a number of advantages for genetic mapping. These include the following: genotyping of each strain is required only once; multiple individuals from each strain may be phenotyped to reduce individual, environmental, and measurement variability; multiple phenotypes can be assessed on the same genetic background. Also, as recombination events are more dense in RIS than those occurring in any one meiosis, greater mapping resolution can be achieved.

5.2.8 Congenic Strains

Congenic rats and mice are generated to obtain strains that differ by a specific chromosomal region, which often contains only a few specified genes, or ideally by a single gene (Figure 5.2) [27]. Two inbred lines are crossed to make an F_1 generation, which is then backcrossed to one of the parental inbred strains. Backcrossing takes place for at least 10 generations in order to remove contaminating background heterozygosity while maintaining heterozygosity within the chromosomal region of interest. After at least 10 backcross generations, brother × sister mating is carried out to achieve homozygosity within the congenic interval. A speed congenic strategy can be used to significantly reduce the time taken to produce a congenic strain (from 4 years to 18 months) [28]. This is achieved by genotyping each backcross generation with 60–100 microsatellite markers evenly spaced throughout the background genome and then choosing animals with the lowest heterozygosity from which to breed and produce the next backcross generation.

Congenic strains are powerful tools for confirming the existence of QTLs identified by genome-wide scans, and production of congenic substrains allows dissection of the region of interest and aids functional studies of candidate causal genes.

5.2.9 Consomic Strains

Consomic strains are produced by repeated backcrossing of a whole chromosome, such as X or Y, onto an inbred strain. They are generated using a strategy similar to that used for congenic strain production (Figure 5.2) [27,29].

5.2.10 Transgenic Rodent Models

Mice and (more recently) rats can be genetically modified using a number of different approaches. These approaches include gene knockout, gene overexpression, conditional/inducible gene overexpression/inactivation, and tissue and/or time specific expression or knockdown [30].

Transgenic models are important tools for studying the function or regulation of a specific gene of interest and for modeling human diseases caused by dominantly acting mutant proteins (e.g., Alzheimer's disease) [31].

There are two main methods for generation of transgenic rodent models [10,31]. The first is pronuclear microinjection, where foreign DNA is introduced directly into the egg, just after fertilization. The DNA is microinjected into the large sperm-derived pronucleus, where it integrates as multiple copies at a random position in the genome, often after one or two cell divisions have occurred. If the transgenic cells contribute to the germ line, some transgenic eggs or sperm will be produced and the next generation will be fully transgenic (Figure 5.3).

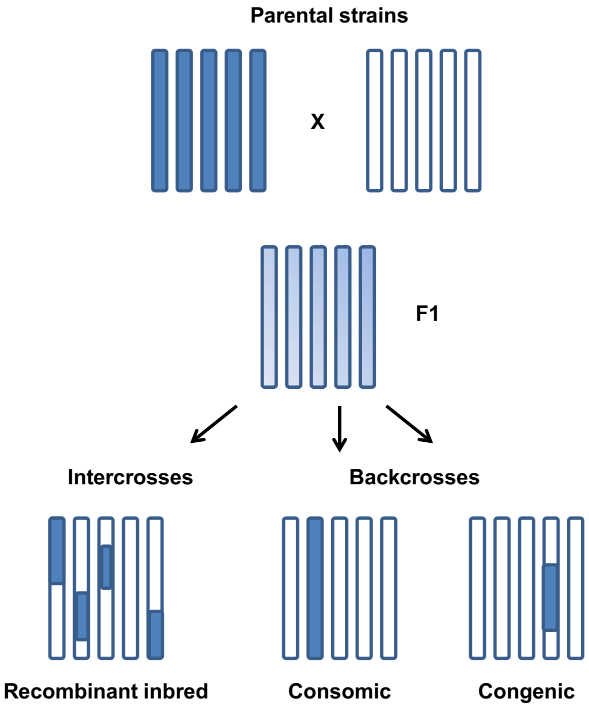

FIGURE 5.2 **Breeding strategies.** These strategies are used to generate recombinant inbred, consomic, and congenic strains.

The second method is the introduction of DNA into embryonic stem cells (ES cells). These are derived from very-early-stage embryos that can differentiate into all types of cell when introduced into another embryo. Similarly to pronuclear microinjection, DNA introduced into ES cells may integrate randomly within the genome. However, if the introduced DNA is similar in sequence to part of the host genome, it may undergo "homologous recombination" and integrate as a single copy at a specific site. ES cells colonize the host embryo and often contribute to the germ line, resulting in the production of some sperm carrying the foreign DNA. When these transgenic sperm fertilize a normal egg, transgenic offspring are produced with the same newly introduced DNA in every cell.

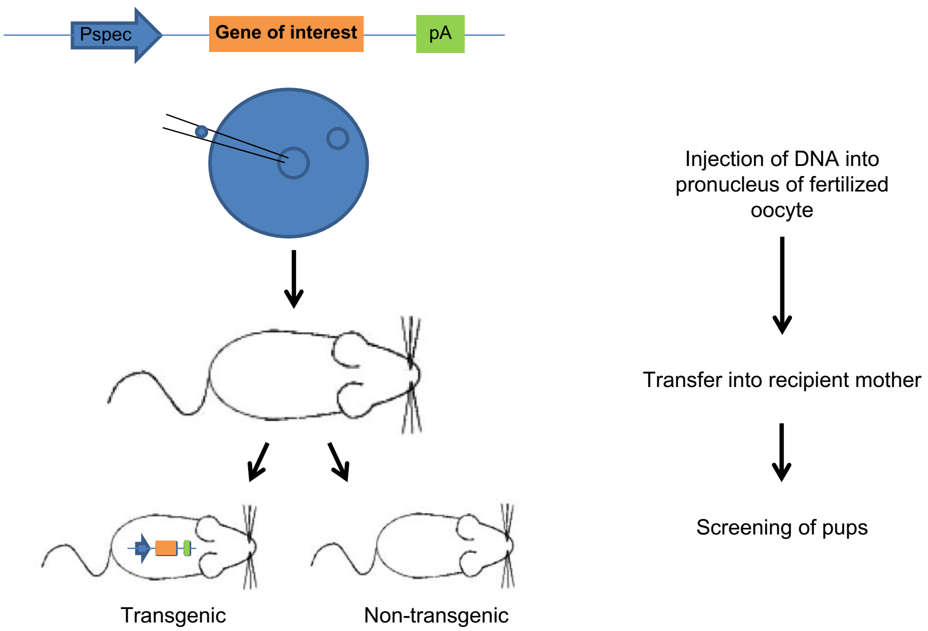
5.2.10.1 *Cre-LoxP Technology*

Because of early embryonic lethality, it is not always possible to generate viable transgenic mice using conventional knockout techniques. To overcome this problem, the Cre-Lox recombinase system was developed [32]. Cre-Lox recombination is a sophisticated site-specific recombinase technology that allows DNA modification to be targeted to a specific cell type or to be triggered by a specific external stimulus. Cre is a 38 kDa recombinase protein from bacteriophage P1 that catalyzes recombination between LoxP sites. LoxP sites are specific sequences of 34 base pairs (bp) consisting of an 8-bp core sequence, where recombination takes place, and two flanking 13-bp inverted repeats [31]. Since Cre gene and LoxP sites are not native to the mouse genome, they have to be introduced by transgenic (ES cell) technology [32]. Typically Cre and LoxP strains are developed separately and crossed to produce a Cre-Lox strain.

There are four main categories of Cre and LoxP strains of mice: (1) Cre-expressing strains, which contain a transgene that expresses Cre under the control of a widespread (general) or tissue-specific (conditional) promoter. They are used to produce general or conditional knockouts, respectively; (2) inducible Cre strains containing a transgene that expresses a modified form of Cre recombinase that is nonfunctional until an inducing agent (e.g., doxycycline, tetracycline, RU486, or tamoxifen) is administered at a specific time; (3) LoxP-flanked (floxed) strains, which contain LoxP sites flanking (on each side of) a critical portion of a target gene or genomic region of interest; (4) Cre reporter strains, which contain LoxP sites in combination with fluorescent or lacZ marker proteins used to determine (visualize) successful recombination and/or alterations in gene expression.

5.2.10.2 *Recent Transgenic Advances*

Zinc-finger nuclease (ZFN) technology directly allows targeted mutagenesis at the 1-cell-stage embryo; therefore, embryonic stem (ES) cells are not required. This process makes model generation much faster and avoids background



Pspec

FIGURE 5.3 **Producing transgenic mice.** The schematic shows a transgenic construct containing a specific promoter (Pspec), the gene of interest, and a polyadenylation signal (pA). This construct is injected into fertilized oocytes to be subsequently transferred into pseudo-pregnant recipient mothers. Pups are then screened for integration of the transgene. *(Modified from Bockamp E, Maringer M, Spangenberg C, Fees S, Fraser S, Eshkind L, Oesch F, Zabel B. Of mice and models: improved animal models for biomedical research. Physiol Genomics. 2002 Dec 3;11(3):115–32.)*

strain limitations. Unlike ES cell transgenesis, ZFN technology is directly applicable to the rat and has been used in recent years to successfully create numerous transgenic rat models on a variety of genetic backgrounds [33,34].

Zinc-finger proteins are well-characterized DNA binding proteins that, for transgenic purposes, have been coupled with a Fok1 endonuclease and designed to recognize and cleave specific DNA sequences. ZFNs are utilized to generate sequence-specific double-strand breaks that are repaired by error-prone nonhomologous end joining (NHEJ) or high-fidelity homologous recombination (HR) [35,36]. Specific DNA cleavage is achieved by varying the zinc-finger domains, as each zinc finger interacts with a particular triplet of DNA base pairs. Combining different zinc fingers permits specific binding to 9–12 bp motifs. Double-stranded breaks occur when two ZFNs bind to the target DNA, bringing their nuclease domains together. One early example of successful ZFN-mediated genetic disruption in the rat includes targeting to endogenous immunoglobulin M (IgM) and Rab38 genes as well as to an integrated GFP reporter gene [33]. ZFN technology is also successfully utilized in *Drosophila* and zebrafish [36].

More recently, transcription activator–like effector nucleases (TALENS) have been used for efficient targeted genome editing. TALENS are similar to ZFNs, comprising a nonspecific Fok1 nuclease domain fused to a customizable DNA-binding domain. They are easily and rapidly designed and have been shown to have high success rates, which makes them suitable for use by nonspecialist researchers [37,38].

Other strategies for producing knockout animals include chemical mutagenesis and the use of mobile DNA elements (transposons and retrotransposons). Chemical mutagenesis using N-ethyl-N-nitrosourea (ENU) is a method of random mutagenesis used in mice and rats [39–41]. ENU is an alkylating agent that transfers its ethyl group to nitrogen or oxygen radicals in DNA, resulting in base mispairing that causes base pair substitution. ENU mutagenesis creates one base pair change in any given gene in every 200–700 gametes. ENU is injected into male mice that are then bred with wild-type females to produce mutant offspring. The offspring are phenotyped, and, once recognized, the causative mutation is mapped by positional cloning [40,42].

Another strategy for targeted gene knockdown is by RNA interference (RNAi) [43]. RNAi is a highly conserved, naturally occurring mechanism of gene suppression found in plant, yeast, and mammalian cells. It has evolved as a valuable biological tool for gene identification and for studying post-transcriptional gene function. RNAi is mediated by naturally occurring endogenous or synthetic exogenous short interfering RNAs (siRNAs), which typically consist of 21–24-nucleotide duplexes. The antisense siRNA strand is incorporated into a RNA-induced silencing complex (RISC), which then targets complementary mRNA sequences in the cytoplasm. mRNA is then cleaved by RNase at sites not bound by siRNA, thus preventing protein translation [44]. siRNA offers many unique features over traditional methods of inhibition (i.e., chemical inhibitors), including sequence specificity, high efficacy, and the ability to target a large number of genes; however, one drawback is its limited delivery to target cells *in vivo*. Unprotected or naked siRNA is able to penetrate cell membranes when injected locally or systemically, but it is rapidly broken down by plasma nucleases [45]. One method shown to improve systemic delivery of naked siRNA to target organs is hydrodynamic tail vein injection, which involves rapid delivery of a large volume of siRNA plus transfection reagent by tail vein or femoral vein. Alternative *in vivo* delivery methods include viral and bacterial vectors, nanoparticle technology, and liposomes, which have all been used with varying success. Differential uptake by various organs depends on the delivery technique, and this should be taken into account when deciding on the most appropriate method of delivery for *in vivo* siRNA.

5.3 NONRODENT MODELS OF HUMAN DISEASE

The zebrafish is becoming an increasingly popular model organism in pharmacogenomics and network analysis. It possesses many features that make it a highly useful model system. Adults are relatively small, inexpensive, and easily housed and maintained in large quantities. They are easily mated under laboratory-controlled conditions, with each pair producing several hundred eggs per mating. The embryos are transparent, allowing easy visualization of fundamental developmental processes. They develop rapidly, and by 5 days post-fertilization larvae have developed the majority of their internal organs, including the liver, pancreas, and a complex vascular network. This relatively short generation time makes genetic screens easier, faster, and cheaper than they are with mice. Thus the zebrafish is currently one of the main model systems for drug discovery and validation. Novel methods to validate potential drug targets in zebrafish include morpholino antisense knockdown technology and target-selected mutagenesis [46].

A variety of human diseases have been modeled on zebrafish. For example, Tanaka et al. [46] developed a zebrafish cardiac failure model. Antisense molecules such as morpholino phosphorodiamidate oligonucleotides (MOs) and peptide nucleic acids (PNAs) have been demonstrated to effectively knock down specific gene function in zebrafish. Translation-blocking MOs interfere with the function of spliceosomes, leading to exon skipping or the use of cryptic splice sites, which results in aberrantly spliced mRNA. The development of *in vivo* assays that are related to human heart failure may lead to the discovery of novel potential drug targets.

In this section, a wide variety of rodent and nonrodent models of human disease have been described, together with a range of applicable gene modification techniques. The choice of gene modification approach will depend, in part, on the gene and organ system of interest and on the relevance of the animal model's biochemistry and physiology to that of the human disease under investigation.

5.4 GENETIC/GENOMIC RESOURCES

There are extensive, publicly available databases on mouse, rat, and zebrafish genetics. Within the research community, distribution and sharing of genetic/genomic datasets is actively encouraged.

A list of the most widely used databases is as follows:

- The Mouse Phenome Database has data on a wide range of strain characteristics, searchable by subject area (e.g., behavior, blood, bone, development), strain, intervention, study design, and so forth (http://www.phenome.jax.org).
- The Mouse Genome Informatics database has data on genes, phenotypes, disease models, gene expression, gene function, pathways, recombinases, strains and SNPs, tumors, and orthology (http://www.informatics.jax.org).
- The International Mouse Strain Resources (IMSR) database is a searchable database of mouse stocks and strains available worldwide (http://www.findmice.org).
- The JAX mice database provides extensive information on mouse genetics, specifically relating to mice maintained by the Jackson Laboratory, Bar Harbor, Maine (http://www. jaxmice.jax.org).
- The Rat Genome Database (RGD) provides a comprehensive database on rat genetics. (http://rgd.mcw.edu, RGD). RGD curates and integrates rat genetic and genomic data and provides free access to support research using the rat as a genetic model for the study of human disease. RGD works in collaboration with the Mouse Genome Database (MGI), NCBI, UCSC, EBI, RGSC, Baylor College of Medicine, SWISS-PROT, BIND, RatMap, and the Phys-Gen PGA [47].
- The NBRP-Rat Phenome Database provides functional characterization (phenome database) for deposited rat strains at the National Bio-Resource Project, Japan. (http://www.anim.med.kyoto-u.ac.jp/nbr/phenome.aspx).
- The Zebrafish Neurophenome Database (ZNP) (http://www.tulane.edu/~znpindex/).
- The European Zebrafish Resource Centre is a public database of available mutant stocks that can be immediately requested from a link through the model organism database, ZFIN (http://zf-health.org/data/databases.html).
- All data from initial phenotyping of knockout mutants is made publicly available through the website of the Zebrafish Mutation Project. Transcript counting results

are publicly available through a custom interface based on ArrayExpress. Information on enhancer elements, synteny blocks, and epigenetic marks can be obtained for any region of the human genome through Ancora, a custom genome browser.
- All information from gene expression mapping of the brain is released through a custom-designed online neuroanatomy atlas, ZebrafishBrain.org (developed in the ZF-MODELS project) and through other databases.

5.5 ETHICAL ISSUES OF ANIMAL EXPERIMENTATION

Since 1986, the European Union has had in place specific legislation covering the use of animals for scientific purposes. On September 22, 2010, the EU adopted Directive 2010/63/EU, which updated and replaced the 1986 directive, 86/609/EEC, on the protection of animals used for scientific purposes. The aim of the new directive was to strengthen legislation and improve the welfare of animals needed for scientific research, as well as to firmly anchor the principle of the Three Rs (Replace, Reduce, and Refine the use of animals) in EU legislation. Directive 2010/63/EU took full effect on January 1, 2013.

In the United Kingdom, an ethical framework for the use of animals in research has been written into law by implementation of the Animals (Scientific Procedures) Act 1986. It exceeded the requirements of the European Union's Directive 86/609/EEC on the protection of animals used for experimental and other scientific purposes. The U.K. act requires that proposals for research involving animals be fully assessed in terms of any harm to the animals. This involves detailed examination of the procedures and experiments and the numbers and types of animal to be used. The proposed experimental procedures are then weighed against the potential benefits of the project. Before the introduction of Directive 2010/63/EU, this cost–benefit analysis was almost unique to U.K. animal research legislation; only German law had a similar requirement. However, the adoption of Directive 2010/63/EU has harmonized legislation across Europe [48].

Before undertaking any research involving animal models in the United Kingdom, it is an absolute requirement that the three R's be considered to fully justify the plan of work and to obtain approval of the project proposal by both local ethics committees and the Home Office Inspector [49,50] ([49,50]). (For further information, the websites http://www.nc3rs.org.uk and http://www.homeoffice.gov.uk/comrace/animals/further info.html may be consulted) The three Rs are as follows.

5.5.1 Replacement

Wherever possible live animals should be replaced by non-sentient or less sentient alternatives such as cell cultures, invertebrates, or mathematical models. There are many examples showing that this can be successful:

- Rabbits and mice were previously used to assay batches of insulin, but now this can be done chemically.
- Monoclonal antibodies were grown as ascites tumors in mice, but this is now done *in vitro*.
- In toxicity testing, there are a number of tests, such as the Ames test for mutagenesis, that, at least partially, replace studies in live animals.

5.5.2 Refinement

Pain, distress or lasting harm should be minimized.

- Anaesthesia and analgesia should be used in surgery.
- Humane end points should be used when death is the expected outcome.
- Tumors should not be allowed to grow to an excessive size.
- Animals should be protected from disease.
- An enriched environment with space for natural behavior should be provided.
- Food and water should be withdrawn only for strictly limited periods.
- Social animals, such as mice and rats, should be housed with other animals (a legal requirement under Directive 2010/63/EU).

5.5.3 Reduction

Use the minimum number of animals consistent with achieving the objectives of the study:

- Develop a research strategy with clearly defined objectives that can be achieved with available resources.
- Choose an animal model capable of answering the question being investigated.
- Undertake experiments that use neither too many animals, so that some are wasted, nor too few, so that important effects are missed.
- Carry out the correct statistical analysis of the results, including summary statistics such as means and standard deviations, as well as indicators of uncertainty, such as significance levels and confidence intervals.

5.6 CAUTION AND LIMITATIONS

Animal models yield important insights into the genetic basis of human diseases, and they provide a test bed for pharmacological treatments. Nonetheless, investigators must carefully consider their choice of model: no single model perfectly recreates the human disease, and there are related considerations of cost, infrastructure, and specialized personnel. Taking these considerations into account, experimenters need to select models that best reproduce the aspect of disease being investigated. In particular, when moving from bench to bedside it is essential to test procedures in relevant models that yield highly reproducible results. These limitations notwithstanding, the range of animal models available today ensures that it will always be possible to devise an appropriate strategy where animal models remain the best tools for advancing understanding of the mechanisms of human disease and identification of appropriate therapeutics.

As pharmacogenomics using animal models becomes increasingly important in preclinical drug development, improvements to all facets of it will be made. Technology improvements will continue to increase the sensitivity, speed, and accuracy with which differentially expressed genes are identified. Genome sequencing will incrementally enhance the quality of annotated DNA and protein databases and will facilitate functional characterization of differentially expressed genes [51].

Inbred strains are a useful tool for understanding the mode of action of pharmacological agents or toxic substances, and for the identification of molecular pathways that confer susceptibility to therapeutic or adverse events. *In vivo* pharmacogenomic screens have often been carried out in single inbred rodent strains in order to standardize the genotype and limit as many variables as possible. This approach provides mechanistic information in a single genetic background. However, the human situation is far more complex, with diverse genetic backgrounds and uncontrolled environmental effects. Interpretation and translation of data generated from a single inbred strain may lead to generalizations and the inability to distinguish small biologically relevant changes from background variation [2,52]. The use of various models will allow assessment of gene–environment interaction and determination of the genetic causes of inter-individual variability.

5.7 APPLICATIONS OF *IN VIVO* MODELS IN PHARMACOGENOMIC RESEARCH

Over the past decade, pharmacogenomics has benefited greatly from technological advances that have allowed the sequencing of mammalian genomes and the development of multilevel "systems" (high-throughput "polyomic") approaches. For example, gene expression arrays have allowed a global view of transcriptional changes in response to pharmacological intervention or xenobiotic exposure [53,54]. These arrays, in combination with panels of inbred rodent models, have determined whole-genome response signatures, identifying gene clusters functioning within the same biological pathways.

5.7.1 Quantitative Trait Mapping

When embarking on an investigation into the genetic basis of disease, drug response, or toxicity, it is not known where in the genome the causative genes may lie. One approach is to search for evidence that the responsible genes are located within specific chromosomal regions, by detecting correlations between the phenotype and genotype at loci throughout the genome. This approach is known as quantitative trait mapping, and it allows the detection of chromosomal regions harboring genes responsible for disease or drug susceptibility [3,55,56]. Standard intercrosses between inbred strains of rats or mice have been used successfully for mapping quantitative trait loci (QTL). This is carried out by cross-breeding two inbred strains to produce a genetically segregating population that demonstrates quantitative variation in the phenotype of interest. The quantitative phenotype is measured in each individual, and the individuals are then genotyped at a number of genetic markers. A statistical assessment (e.g., the logarithm of the odds (LOD) score) is calculated between the phenotypic values and each marker.

QTL mapping has been used to investigate numerous disease and drug susceptibility traits. One example is the mapping of a mouse limbic seizure susceptibility locus on mouse chromosome 10 by investigating susceptibility to pilocarpine, a muscarinic cholinergic agonist that models human temporal lobe epilepsy [57]. Another example is the identification of QTLs for alcohol-related behavioral traits [58,59].

5.7.2 Identification of eQTLs

Gene expression QTL (eQTL) mapping is a relatively recent technique for assessing associations between transcript expression and genotype in order to identify regulatory locations within the genome [60]. eQTL analysis has shown that genetic regulation of gene expression is a key contributor to population diversity, and it has made an important impact on our understanding of the effects that genetic polymorphisms have on interindividual, tissue-specific variability in physiological processes [61]. The investigation of genes underlying eQTL hotspots allows investigators to determine regulatory candidates of transcription. eQTLs may act in *cis* (locally) or *trans* (at a distance) to a gene. Although *trans* effects have been shown to be globally important, their individual effects are small and therefore their genome-wide identification remains a challenge. eQTL mapping is hypothesis-generating with regard to transcriptional regulation and the discovery of gene networks or pathways of drug susceptibility. However, it can also be used to narrow down a list of genes for further investigation.

While genome-wide association studies (GWAS) in humans tend to focus almost exclusively on statistical evidence (often giving lesser weight to biological plausibility), animal models provide an opportunity to investigate the functional consequences of causal alleles. The production and use of transgenic models allow the investigation of individual or multiple clusters of candidate genes on the phenotype of interest. The increasing complexity of the transgenic lines available, including knockout, knockin, conditional (i.e., the ability to switch a gene on and off), and tissue/organ-specific, allows detailed examination of "causal" variants.

5.8 RODENT MODELS IN PHARMACOGENOMICS

This section provides a snapshot of cases in which animal models have been used successfully in pharmacogenomic strategies.

5.8.1 Bipolar Disorders

Like many neuropsychiatric disorders, bipolar disease is a complex polygenic disorder with variable penetrance, which has made unraveling its underlying genetics particularly difficult [62]. Illness-causing mutations of bipolar disease are often detrimental to reproductive potential and therefore are evolutionarily selected against. This results in minor frequency alleles that require very large sample sizes to achieve statistical significance. Bipolar disorder is further complicated by phenotypic heterogeneity and is influenced by environmental factors [63].

The combination of both human clinical studies and animal research has been crucial to the progress made in understanding the genetic and neurobiological basis of bipolar disorders. The integration of gene expression data from rodent models with human genetic linkage/association data, together with findings from human postmortem brain tissue, has allowed translational validation of findings, resulting in the identification of candidate genes, pathways, and mechanisms for subsequent targeted, hypothesis-driven research [64].

Some of the behavioral signs and symptoms of bipolar disorder can be achieved by methamphetamine administration in rodents, resulting in manic features in the activation phase and depressive features in the withdrawal phase with a single dose [65]. More complex psychosis is achieved with administration of multiple methamphetamine doses [66].

Previous microarray studies by Niculescu et al. [65], in a mouse model, where methamphetamine was used as a stimulant and co-treated with the mood stabilizer valproate, identified a prioritized list of bipolar candidate genes. Results from this pharmacogenomic approach in mice were cross-validated with data generated from human bipolar genetic studies using a strategy termed "convergent functional genomics." Niculescu et al. utilized this translational pharmacogenomic approach as a tool for tagging genes that have pathophysiological relevance. These findings were recently extended to include additional GWAS datasets, and recent evidence from other lines of work, including human post-mortem data, providing the most comprehensive integration of genetics and functional genomics in the field of bipolar disorders [64,67]. Through these studies, six top candidate genes (ARNTL, MBP, BDNF, NRG1, RORB, and DISC1) were identified that merit future follow-up as either novel or existing therapeutic targets.

Moreover, this important study has allowed a panel of single-nucleotide polymorphisms (SNPs) to be generated based on the top identified candidate genes. Based on this panel, a genetic risk prediction score (GRPS) for bipolar disorder was developed and used in an independent cohort to demonstrate that the GRPS differentiates between patients with bipolar disorder and normal controls in both European American and African American populations.

5.8.2 Anxiety Disorders

Niculescu et al. [68] used a similar pharmacogenomic approach to identify candidate genes as well as potential blood biomarkers for anxiety disorders. In this study they used a mouse model treated with the anxiogenic drug yohimbine and the anti-anxiety drug diazepam to examine gene expression changes in blood and key brain regions for anxiety (prefrontal cortex, amygdala, and hippocampus) [68]. The microarray results were analyzed using a convergent functional genomics (CFG) approach, which integrated the researchers' findings with published human and animal model data. This translational strategy of cross-matching and prioritizing findings identified top candidate genes (including FOS, GABBR1, NR4A2, DRD1, ADORA2A, QKI, RGS2, PTGDS, HSPA1B, DYNLL2, CCKBR, and DBP), brain-blood biomarkers (such as FOS, QKI, and HSPA1B), pathways (such as cAMP signaling), and mechanisms for anxiety disorders.

Importantly, this study demonstrated a major overlap between top candidate genes for anxiety and candidate genes for schizophrenia and bipolar disorder, as well as alcoholism previously identified by the same group. This suggests a possible molecular basis for the frequently observed clinical co-morbidity and interdependence between anxiety and other major psychiatric disorders. Notably, PDE10A and TAC1 are at the overlap of all three major psychiatric domains and may be of major interest for drug development [69–71].

In terms of pharmacotherapy and drug development, some of the candidate genes identified in this study encode for proteins that are modulated by existing pharmacological agents, which may suggest future avenues for rational polypharmacy using currently available agents.

5.8.3 Pharmacogenomics Using Xenograft Mouse Models of Acute Leukemia

Acute myeloid leukemia (AL) is a heterogeneous malignant pathology with a poor global prognosis. The disease occurs when hematopoietic progenitor cells undergo malignant transformation into primitive, undifferentiated cells with abnormal longevity [72]. These cells proliferate abnormally, replacing normal bone marrow tissue and hematopoietic cells. Despite significant therapeutic advances in AL, a large number of patients relapse and frequently present with drug-resistant and refractory leukemia. Due to genetic therapeutic options with particular focus on targeted therapies.

Xenograft mouse models are widely used to identify and test new therapeutic targets and strategies for acute leukemia [72,73]. These models are generated in immunodeficient mice (i.e, NOD/SCID (NS) and NS IL2Rgamma (NSG)), which allow the engraftment of human blast cells via injection into the tail vein or retro-orbital sinus. Prior conditioning by irradiation is often used to improve the engraftment rate. However, it has been shown that lifespan is prolonged and vascular injury is reduced in nonirradiated NGS mice [74]. NS or NSG mice injected with primary or leukemic cell lines strongly display the fundamental biological characteristics of the original human disease. Disease progression is assessed by immunophenotyping of human cells in mouse peripheral blood by flow cytometry analysis and/or by histopathology of bone marrow, spleen, and other organs after sacrifice. Immunocompromised mouse models are valuable tools for understanding the effects of individual drugs or drug combinations at the molecular level, and they provide an important opportunity for pharmacogenomic analysis of AL [72].

One example of evaluation of the xenograft mouse model for pharmacogenomic assessment in AL is the study by Bhadri et al. (2011) [75]. Glucocorticoids (GCs), such as prednisolone and dexamethasone, are critical components of multi-agent chemotherapy protocols used in the treatment of acute lymphoblastic leukemia (ALL) [76] because of their ability to induce apoptosis in lymphoid cells. In the study by Bhadri et al. [75], the NOD/SCID xenograft mouse model was evaluated as a tool to investigate glucocorticoid-induced gene expression. Cells from a glucocorticoid-sensitive xenograft derived from a child with B-cell precursor ALL were inoculated into NOD/SCID mice. When highly engrafted (>70% 8–10 weeks post-transplantation), the mice were randomized into groups receiving either dexamethasone (15 mg/kg by intraperitoneal injection) or vehicle control. Leukemia cells were harvested from mice spleens at 0, 8, 24 or 48 h, and gene expression was analyzed on Illumina WG-6_V3 chips.

The 8 hour dexamethasone-treated time point demonstrated the highest number of significantly differentially expressed genes, with fewer observed at the 24 and 48 h time points and with minimal changes seen across the time-matched controls. Dexamethasone treatment identified 173 upregulated genes and 25 downregulated genes. Upregulated genes included those known to be involved in GC response (TSC22D3, SOCS1, FKBP5, MAPK5, ZBTB16). At the later time points, most of the differentially expressed genes are involved in cell cycle progression and apoptotic pathways, consistent with growth arrest. When compared to publicly available datasets of glucocorticoid-induced gene expression from an *in vitro* cell line study and from an *in vivo* study of patients with ALL, expression changes in the 8 h xenograft samples showed a similar response to patients treated with glucocorticoids. It was concluded that the NOD/SCID ALL xenograft mouse model provides biologically relevant insights into glucocorticoid-induced gene expression, in a consistent, reproducible, and clinically relevant model system.

5.8.4 Pharmacogenomics of Pain and Analgesia

Pain severity ratings and the analgesic dosing requirements of patients with apparently similar pain conditions may differ considerably between individuals. Genetic, environmental, and epigenetic factors have been implicated in interindividual differences in pain sensitivity [77]. Evidence of a genetic component of pain modulation comes from rodent heritability studies as well as from familial aggregation and twin studies in humans. More than 350 candidate pain genes have been identified as potentially contributing to heritable differences in pain sensitivity [77].

A study by Tapocik et al. (2009) [54] identified candidate genes and networks specifically associated with analgesic tolerance to morphine. The researchers used a congenic strategy, whereby only those genes specifically correlated with the trait of interest were identified as candidate genes significantly influencing the development of morphine tolerance. Two inbred mouse strains (C57BL/6J (B6), DBA2/J (D2)) and two reciprocal congenic strains (B6D2, D2B6), in which the proximal region of chromosome 10 (Chr10) was introgressed into opposing genetic backgrounds, were used in a behavior genetics approach. Therapeutically relevant doses of morphine were administered to the mice, and acute analgesic sensitivity to morphine was measured by the hot-plate test. Tolerance to morphine developed most rapidly in B6 mice followed by the B6D2 congenic strain (on the D2 genetic background); it did not develop in the D2 mice and developed only slightly in the D2B6 congenic strain (on the B6 genetic background). This indicated a strong influence of the proximal region of Chr10 in the development of tolerance.

In conjunction with behavioral studies, large-scale gene expression profiling was performed using brain sections from the prefrontal cortex (PFC), ventral striatum (VS), temporal lobe (TL), and periaqueductal grey (PAG) regions. The microarray comprised the National Institutes on Aging KO set of 15,247 cDNA clones [78] and the National Institutes of Mental Health Brain Molecular Anatomy Project set of 11,136 cDNA clones (representing ~21,000 distinct mouse genes). Canonical pathway and network analyses were used to identify significant candidate genes for predisposition and tolerance. Canonical pathway analysis of the morphine-responsive genes suggests a significant role for neuroadaptive processes in response to chronic morphine administration (i.e., LTP, axonal guidance, ephrin, neuroregulin pathways).

Network analysis was used by Tapocik et al. [54] in identifying highly interconnected genes to provide insight into molecular events that predispose or are causally related to the development of tolerance. A potential gene network was identified in the PAG in which 19 of 34 genes identified were strongly associated with tolerance. Eleven of the network genes were found to reside in quantitative trait loci previously associated with morphine-related behaviors, whereas seven were predictive of tolerance (morphine-naive condition). Overall, the genes modified by chronic morphine administration showed a strong presence in canonical pathways representative of neuroadaptation. A potentially significant role for micro-RNA and epigenetic mechanisms in response to chronic administration of pharmacologically relevant doses of morphine was highlighted by candidate genes Dicer and H19. Expression of H19 appears to decrease in the genotypes that become tolerant to morphine and increase in those that do not.

5.8.5 Pharmacogenomics and PAH

Pulmonary arterial hypertension (PAH) is a heterogeneous disorder, and it is widely recognized that different clinical groups of PAH exhibit different degrees of responsiveness to the same therapeutic agents. For example, PAH associated with scleroderma and other inflammatory disorders has a generally poorer response than idiopathic PAH [79]. A proof-of-concept study was carried out by Said et al. in 2011 [80] demonstrating that therapeutic responses in different PAH models are reflected by differential underlying gene expression patterns. This study showed that PAH may benefit from targeted therapies based on unique genomic features. In the study, two experimental models of the disease were investigated: mice with deletion of the vasoactive intestinal peptide gene (VIP$^{-/-}$) and Sprague Dawley rats injected with monocrotaline (MCT). These two models express comparable phenotypic features, with the MCT model showing generally more severe PAH [81,82]. Both models were treated with the same drug, vasoactive intestinal peptide (VIP), and the phenotypic and genotypic responses in each were analyzed. Microarray expression profiling in lungs from VIP KO mice demonstrated uniform expression of a single set of gene alterations, comprising upregulation of vasoconstrictor/proliferative genes, downregulation of vasodilator/ antiproliferative genes, and upregulation of inflammatory genes. Treatment of the mice with VIP corrected the key features of PAH, including elevated pulmonary artery pressure, vascular remodeling, right ventricular hypertrophy, and lung inflammation, and it reversed the genetic expression changes toward normal values. However, in the MCT model VIP treatment incompletely corrected the phenotypic changes and was only partially successful in reversing the genotypic abnormalities. MCT genotypic analysis showed two distinct sets of expression alterations: one similar to that in VIP$^{-/-}$ mice (i.e., alterations that promote vascular remodeling and inflammation) and the other suggesting an effort to modulate the PAH.

The authors concluded that, despite its limited scope, this proof-of-concept study provided evidence to support the applicability of pharmacogenomics in PAH. The correlation of genomic analysis with drug response in two animal models demonstrated the usefulness of genomic information in selecting appropriate, targeted therapy in PAH and in predicting therapeutic outcome. However, these findings in rodent models need to be validated using lung tissues from human patients with different forms of PAH.

5.8.6 Pharmacodynamic/Pharmacogenomic Modeling of Insulin Resistance

Glucocorticoids are secreted by the adrenal cortex and maintain adequate blood glucose levels in order to satisfy the demands of the vital organs, particularly the brain. Among other functions, glucocorticoids increase the synthesis and activity of enzymes in the gluconeogenic pathway in liver and kidney and also control the release of gluconeogenic substrates from muscle and fat. Corticosteroids (CS), which are synthetic glucocorticoids, are used clinically for a wide variety of conditions that require immune and/or inflammatory modulation. However, therapeutic use of corticosteroids is accompanied by a wide range of adverse effects that include muscle wasting, insulin resistance, and hyperglycemia, caused by the magnification of "glucocorticoid-type" pharmacological actions [83].

Studies by Almon et al. [84–88] investigated CS effects on insulin resistance genes in rat skeletal muscle. Acute and chronic administration of methylprednisolone (MPL) was carried out in adrenalectomized Wistar rats. Adrenalectomy was used in order to eliminate circadian oscillation in CS-responsive genes to facilitate effective data mining. On completion of the respective CS dosing periods, microarray expression profiling was carried out in mRNA extracted from the rat gastrocnemius muscle using Affymetrix gene chips. Using two different dosing regimens in a time series format, the researchers were able to produce kinetic/dynamic models for the regulation of the expression of six genes that contributed to CS-induced insulin resistance in skeletal muscle. These genes were identified as insulin receptor substrate-1 (IRS-1), uncoupling protein 3 (UCP3), pyruvate dehydrogenase kinase isoenzyme 4 (PDK4), fatty acid translocase (FAT), glycerol-3-phosphate acyltransferase (GPAT), and endothelin-1 (ET-1). The kinetic models included both direct effects of CS on the genes as well as indirect effects due to the effects of CS on other transcription factors such as MyoD and SREBP-1c.

Importantly, these studies demonstrated the complexity of the underlying mechanisms of CS-induced insulin resistance and the necessity of developing experimentally testable hypotheses (dynamic models) on a genome-wide scale to begin elucidating the implicated regulatory pathways.

5.9 CONCLUSION

No single study that uses an isolated approach will answer the important questions relevant to the molecular, physiological, and clinical consequences of a particular polymorphism. Indeed, it is the collection of studies, which include *in vitro* investigations, human clinical studies, and relevant animal models, that together provide the information necessary to inform a pharmacogenomic strategy for a given drug.

Animal models have greatly improved our understanding of the cause and progression of human genetic diseases, and they have proven to be a useful tool for discovering targets of therapeutic drugs. Investigation of a variety of models, appropriate computational support, and continued improvements in technology will increase the sensitivity, speed, and accuracy with which differentially expressed genes are identified. Genome sequencing will incrementally enhance the quality of annotated DNA and protein databases, and will facilitate functional characterization of differentially expressed genes.

6.1 OVERVIEW

In the post-genome era, there has been a paradigm shift in human genetics and health sciences from the human genome to humanity's genes. In turn, the focus of research has been from individuals toward populations. Different individuals have different genomes in ethnically diverse populations. In terms of gene–environment interaction, mutations or defects in the same gene do not always result in the same clinical outcomes in humans. Likewise, the same polymorphic changes do not always result in the same phenotypes in human physiology. The development and outcome of diseases depend on an individual's genetic makeup interacting with environments such as life style and environmental exposure.

Modern health sciences need unprecedentedly large-scale samples and health data for understanding disease risk factors and therapeutics as well as translating biomedical research into healthcare. Thus, biobanks and next-generation -omics technologies lead to the era of big data, in which personal genetic and health information will be key elements to facilitate the realization of predictive, personalized, preventive, and participatory medicine.

In the field of pharmacogenomics, large numbers of genetic variants underlying drug toxicity and efficacy need to be investigated at the genome-wide level using large numbers of samples and electronic health records. In such efforts, biobanking and biorepositories have been implemented in many areas of public health science, such as discovery science for drug and biomarker development, clinical trials monitoring the effects of drugs on eventual outcomes, and clinical care for therapy. Furthermore, harmonization and data sharing of biobank resources have become a necessity for achieving sufficient statistical power in biobank-assisted pharmacogenomic studies.

Personalized medicine seeks to dissect individuals' responses to environmental stresses or stimuli. In the last decade, a novel *in vitro* LCL-based assay system was developed as a powerful tool to dissect genetic determinants underlying interindividual variations in drug responses and molecular targets of drugs of interest. Despite the limitations of LCLs, pharmacogenomic studies have utilized the *in vitro* cell model using LCLs, and the model's utility is increasingly extended to various genomics and pharmacogenomics fields. Especially with the advent of next-generation sequencing technology, more and more RNA-seq data will be generated from various panels of LCLs which will facilitate the elucidation of global landscapes of gene

expression in response to environmental stimuli. Here, LCL applications in pharmacogenomics fields and accompanying methodological issues will be discussed.

6.2 GENERATION OF LCLs

6.2.1 What Are LCLs?

LCLs are EBV-transformed lymphoblastoid B-cell lines, which can be easily established by EBV infection or derived spontaneously from peripheral blood B lymphocytes. It is easy to generate LCLs by EBV infection from a small quantity (1−5 ml) of whole blood of healthy donors or patients; it is also easy to maintain LCL cells in continuous subculture. Thus, LCLs are used as an unlimited resource for various genetics and immunologic studies.

Normal B lymphocytes have a limited lifespan *in vivo* and *in vitro* as other human differentiated cells, possibly because of telomere shortening (telomerase activity decrease). However, spontaneous cellular immortalization has been observed in human somatic cells from patients with genetic disorders [1–4]. Spontaneous LCLs can be generated in tissue culture from human patient tissues, including bone marrow cells [5], tonsils [6], and lymphocytes [7]. The transformation efficiency of spontaneous lymphoblastoid cell lines (SP-LCLs) was increased by tumor promoter treatment [8], radiation [9], and sometimes in cyclosporine-containing medium from EBV-seropositive patients [10].

Generally the EBV-mediated B-cell transformation takes 3–4 weeks from an initial EBV infection to the freezing of propagated cells for permanent storage. It is considered a failure of transformation if EBV-infected B lymphocytes fail to form cell clumps by 8 weeks. In addition, when the LCL is capable of proliferating up to the passage number of 160 during the continuous long-term subculture, it is considered to be terminally immortalized.

6.2.2 EBV-Mediated B-Cell Transformation

6.2.2.1 LCL Generation Protocols

The Epstein-Barr virus (EBV) was first described in 1964 as an etiological agent of Burkitt's lymphoma, which was initially found in the African malaria belt [11]. Several years later, it was demonstrated that EBV can induce *in vitro* transformation of leukocytes [12,13]. EBV belongs to the herpes virus family and infects more than 95% of the adult population; the majority of primary infections occur in early childhood and then become generally subclinical for life. However, in patients with reduced immunity, EBV infection often results in diseases, including post-transplant lymphoproliferative disease (PTLD) in organ transplant patients or oral hairy leukoplakia with nonmalignant hyperplastic lesion of epithelial cells.

As in Burkitt's lymphoma, EBV is implicated in many cancers, including nasopharyngeal carcinoma, Hodgkin's disease, and lymphoproliferative disease with impaired T-cell immunity. EBV has a dual cell tropism mediated through the interaction of viral gp350/220 and cellular CD21/CR2 (also the receptor for the C3d component of complement) on B lymphocytes [14]. The EBV genome encodes over 85 open reading frames in the genome, making up a linear dsDNA molecule of about 172 kb. EBV-positive or -negative cell lines have been established from EBV-related lymphoma tissues [15,16]. These EBV-positive lymphoma cell lines contain a different number of EBV genomes (e.g., 2 copies/cell in Namalwa, 50 copies/cell in Raji, 152 copies/cell in Daudi), compared to EBV-negative lymphoma cell lines with no EBV genome (e.g., Ramos, DG75).

6.2.2.2 Transformation Efficiency

Since it was shown that EBV can selectively transform B lymphocytes to produce immortalized polyclonal B-cell lines *in vitro* [17], many efforts have been made not only to understand the mechanism of EBV-mediated B-cell transformation but also to increase the transformation efficiency of lymphocytes that may be important specifically for population-based biobanking. In gradient fractionations of B lymphocyte subpopulations, the target subpopulations of EBV infection are high-density cells representing small resting B lymphocytes [2].

In contrast, the low-density fractions are enriched for large activated B lymphocytes that are resistant to EBV infection. EBV penetrates all B-cell populations, including resting and activated cells, but only the high-density populations are transformed. Only small portions (~20%) of *in vitro* EBV-infected peripheral blood B lymphocytes exhibit EBNA expression, which is the earliest detectable EBV-encoded nuclear antigen after infection [18]. After EBV infection, their cells are variable in size, morphology, and Ig expression. LCLs become oligoclonal or monoclonal because of the outgrowth of selected cell clones during the EBV transformation and immortalization [19].

During EBV transformation, some factors affect transformation efficiency. Factors contributing to the high success rate of EBV transformation include: processing in a sterile environment against microbial contamination; protecting cross-contamination of cell lines; using high-potency viral supernatant of sufficient titer; using good-quality blood samples (e.g., sufficient number of lymphocytes more than 10^6, not contaminated with red blood cells) [20]. Regression of transformed cultures and the delay between collection and processing of blood samples may also contribute to transformation failure. LCL generation methods are well documented elsewhere [21,22]. Various methods and modifications have been described to generate LCLs (Table 6.1).

TABLE 6.1 Major Achievements and Modifications in Protocols for LCL Generation

Keywords	Achievements/Modificaitons	References
EBV discovery	EBV discovered in Burkitt's lymphoma tissue	[11]
Spontaneous LCL	Spontaneous LCL generation first reported	[23]
EBV transformation	EBV used for leukocyte transformation	[12]
B95.8 strain	EBV producer cell lines generated from marmoset leukocytes	[24]
Selective B-cell transformation	EBV selectively transforms B lymphocytes	[17]
Cyclosporine	T cell immunosuppressant increases transformation efficiency	[6]
Frozen lymphocytes and PHA	Frozen lymphocytes used for EBV infection in the presence of PHA	[25]
Frozen lymphocytes and cyclosporine	Frozen lymphocytes used for EBV infection in the presence of cyclosporine	[26]
Small volume of frozen blood cells	LCL generation tested in the context of biobanking	[5]
FK506	FK506 (T-cell immunosuppressant) promotes proliferation of EBV-infected B cells	[27]

Besides controlling these experimental environments, some treatments (e.g., cyclosporine, phytohemagglutinin, CD19 treatment) have been used to increase the efficiency of EBV-mediated B-cell transformation or to shorten the period of immortalization. For example, cyclosporin A, currently known as an immunosuppressive drug, facilitates *in vitro* outgrowth of EBV-infected B lymphocytes over T lymphocytes to increase EBV transformation efficiency [6,28]. This effect is most probably due to inhibition of the immune T lymphocytes, which is implicated in the spontaneous regression of EBV-infected lymphocytes. As most adults are EBV-seropositive and have regulatory T cells, EBV infection can elicit cytotoxic T lymphocytes in cultures that destroy the EBV-infected cells.

Besides functional inactivation of T cells, transformation efficiency can be enhanced by the enrichment of B cells for EBV infection using magnetic beads that conjugate with anti-CD19 antibody specific to B cells [5]. It is known that cyclosporine A inhibits T cell activation by blocking gene expression of cytokines (e.g., IL-2, IL-4), which results in immunosuppressive activity [29]. Recently, another T cell immunosuppressant, FK506 (Tacrolimus), was used for quicker and more reliable EBV-mediated B-cell transformation with a combination of high titers of EBV virus [27]. In general, one can see clumps of cells by light microscope about a week after EBV infection, but their presence is not a specific indicator of successful EBV transformation. Notably, a recent study showed that successful EBV transformation can be monitored by the presence of CD23^{hi}CD58^{+} cells as early as three days post–EBV infection [30].

Phytohemagglutinin (PHA) is a mitogenic agent that has long been used as a red-cell agglutinating agent, removing red blood cells from leukocyte culture. Studies identified PHA as a T cell mitogen that can trigger cell division transforming rapidly to blast cells. The blastogenesis of T lymphocytes leads to cell death before the cytotoxic T cell response is induced against EBV infection. In fact, pretreatment of cord blood leukocytes with phytohemagglutinin results in a 50% increase in EBV-mediated transformability [18]. PHA is less effective than cyclosporin A when blood is from EBV-seropositive donors [21]. Most HapMap LCLs are established by EBV transformation of peripheral blood mononuclear cells using phytohemagglutinin. For example, most LCLs from Coriell Cell Repositories were established using standard EBV transformation protocols that included mononuclear cell separation by Histopaque-1077 Hybrid Max gradient centrifugation in order to obtain peripheral blood mononuclear cells (PMBCs), and induced lymphocyte divisions by phytohemagglutinin as a mitogen [31].

When a new method for EBV-mediated transformation was developed for cryopreserved lymphocytes, fresh blood samples were no longer necessary for EBV transformation as a starting material [25,32]. This method was primarily based on Gusella's protocol [6], but it was modified to include additional steps such as Ficoll-gradient centrifugation of buffy coats prior to cryopreservation and phytohemagglutinin treatment on EBV infection. The Pressman group's protocol [26] included the following steps, which are different from the Louie and King protocol:

1. Direct separation on a density gradient without first isolating the buffy coat to save time
2. Washing the lymphocytes only twice and at lower speeds to be less harsh on the cells
3. Using cyclosporine a in the transformation step rather than PHA-P
4. Using a controlled-rate cell freezer (cyromed model 700a) for a more consistent and accurate rate of freezing to give a better rate of recovery of frozen cells

6.2.2.3 EBV Producer Cell Lines

The most commonly used EBV producer cell line is the B95-8 cell line derived from EBV-infected leukocytes of marmoset monkey. In humans, EBV-transformed B cells or immortalized lymphoblastoid cell lines restrict replication of the virus and release very few extracellular infectious viral particles. But monkey marmoset leukocytes were successfully transformed to release sufficient amount of infectious EBV virions in cultures [24]. In this EBV-transformed marmoset cell line, B95-8, the release of infectious EBV virus particles were increased during the exponential phase of cell growth, but decreased once the cells reached the stationary phase.

Although the B95-8 cell line (ATCC CRL-1612) is the most popular EBV producer cell line, it is no longer distributed commercially without a permit because it is derived from a primate species listed as endangered by the U.S. Fish and Wildlife Service. As an alternative, EBV-containing supernatants from the B95-8 cell line are distributed by ATCC as VR-1492 (http://www.atcc.com). Thus, the culture supernatant of the B95-8 cell line has been used as an EBV viral source for EBV-mediated B-cell transformations in almost all LCL repositories. Besides the B95-8 cell line, other EBV producer cell lines are occasionally used for EBV-mediated B-cell transformation. These cell lines were established from EBV-related lymphoma cells. For example, the Akata, P3HR1, and BJAB cell lines were derived from human Burkitt's lymphoma cells, and the M-ABA cell line was established from a nasopharyngeal carcinoma.

6.2.3 LCL Generation in Biobanks

6.2.3.1 Current Biobanks

A biobank is generally defined as a collection of human biological samples and associated information organized in a systematic way for research purposes. The traditional concept of DNA and serum banks has evolved to current biobanks in the genetic epidemiological studies, boosting population-based biobanks for healthy donors. In contrast, tissue repositories for cancer research were advanced for the pathology-based human biobanks to foster disease-based biobanks for patients. Although human biobanks have to consider additional, complicated ethical issues regarding human rights and dignity, they are considered to be one of the biological resource centers (BRCs) for which global organizations have developed guidelines dealing with operational and quality issues, biosecurity, collaborations, and so forth. Biobanking and biorepositories have been implemented in many areas of public health, such as drug and biomarker development, clinical trials monitoring of the effects of drugs on eventual outcomes, and clinical care for therapy.

6.2.3.2 Blood Cell Banking for LCL Generation

In general, when population-based biobanks collect blood-derived samples, whole blood samples are stored in liquid nitrogen tanks for EBV transformation for future purposes. To generate LCLs, starting points for EBV-mediated B-cell transformation can be anywhere in the process of peripheral blood fractionation, such as whole blood itself, buffy coats, peripheral blood mononuclear cells (PBMCs) isolated by Ficoll-gradient centrifugation, or purified CD19(+) B cells (Figure 6.1). It was reported that a small quantity of frozen blood cells (as little as 500–800 ul) was successfully used to generated LCLs with a transformation success rate of over 95% [5] (http://www.hpacultures.org.uk/services/gss/EBVtransformation.jsp).

First of all, in order for whole blood to be used for direct EBV transformation, it should be anti-coagulated in citrate- (ACD-) or EDTA-containing tubes. In most cases, the ACD vacutainer is recommended for drawing peripheral blood for later use in EBV transformation. If not used immediately, the blood sample needs to be cryo-preserved in 10% DMSO in liquid nitrogen. However, successful EBV transformation was also achieved when residual clinical blood samples were placed on the bench for a considerable time before EBV infection [33]. Interestingly, the U.K. Biobank's pilot study showed that when blood samples were maintained at room temperature for variable periods of 24 h, 1 or 2 weeks before cryo-preservation and subsequent positive B-cell selection using the Miltenyi autoMACS cell separation station (Miltenyi Biotec), EBV transformation could be achieved at a success rate of 92%, 67%, or 38% for blood samples, respectively [5]. This pilot study provides population-based biobanks with a more cost-effective method based on small volumes (0.5 ml) of cryo-preserved whole blood. Thus, whole-blood samples could be successfully cryo-preserved for the future generations of LCLs to be selectively transformed for future needs.

6.2.3.3 Quality Control of LCLs

Because EBV producer cell lines are used as an EBV source, human lymphoblastoid cell lines are occasionally

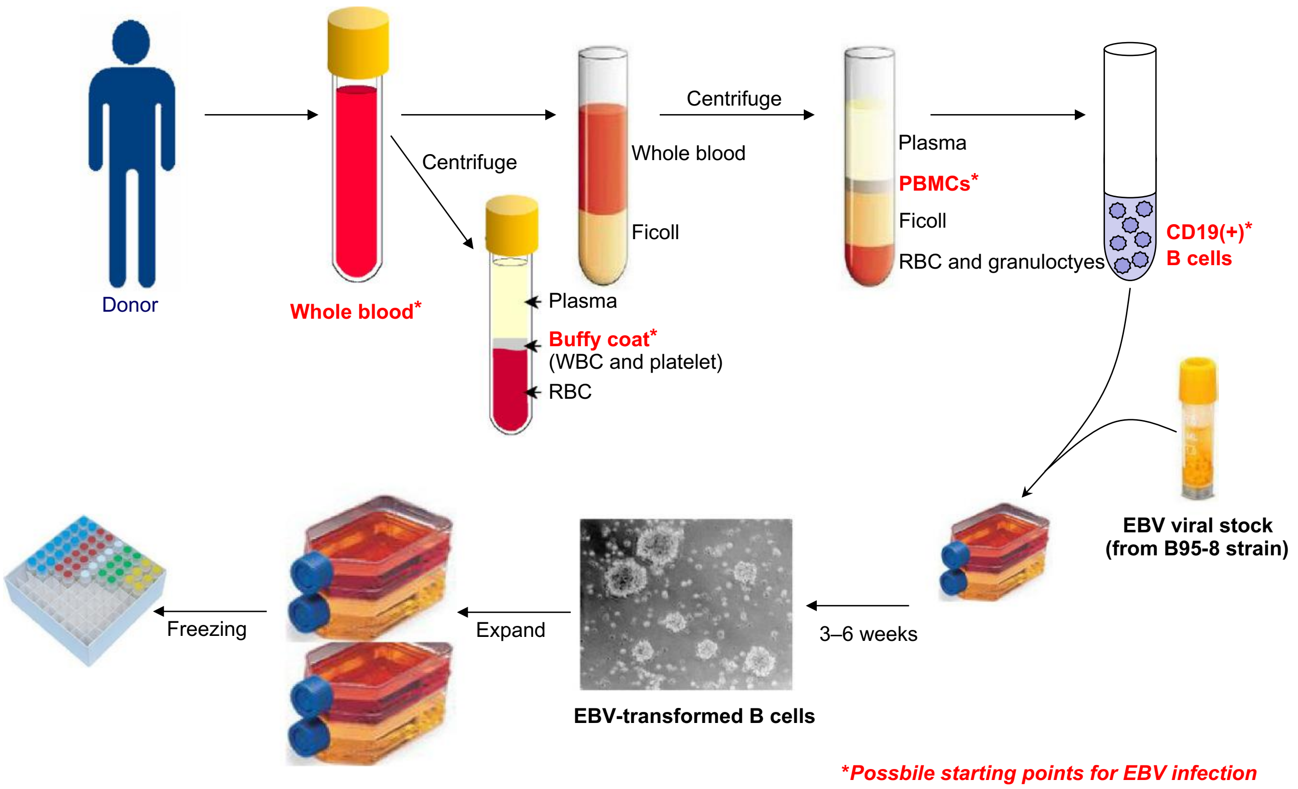

FIGURE 6.1 LCL generation workflow.

contaminated with them during LCL generation. Several standard techniques—DNA fingerprinting by STR (short tandem repeats) analysis, SNP genotyping analysis, human leukocyte antigen (HLA) typing, and the like—should be used for cell line authentication. In addition, large-scale cell repositories often encounter cell line cross-contamination and misidentification. Studies have highlighted the number of cell lines that have been cross-contaminated with another cell line (often older, more well-established cancerous cells) [34,35].

The International Cell Line Authentication Committee (ICLAC) has maintained a database of cross-contaminated or misidentified cell lines [36]. For example, it is known that some 15–20% of cell lines in current use may be cross-contaminated or mislabeled in routine culture [37]. According to MacLeod et al. [35], 18% of 252 cell lines donated to the bank were misidentified or contaminated. Interestingly Drexler et al. [38], reported that some EBV-positive B lymphoblastoid cell lines was misclassified as myeloma cell lines (e.g., IM-9, GM1312, ARH-77) or Hodgkin's lymphoma cell lines (e.g., L-591, RB, RPMI-6666). Besides cell authentication, other quality control measures should be taken for microorganism contamination (e.g., bacterial and mycoplasma) during LCL generation and maintenance. LCLs should be handled using aseptic techniques under the Biosafety Level 2 (BSL-2).

6.2.4 LCL Repositories and Collections

Because the value of LCLs was demonstrated in many applications of genomics and pharmacogenomics and immunological studies, large LCL collections have been established from various populations with different ethnic origins. The most well-known LCL collections are the CEPH pedigrees, the International HapMap populations, and the Human Variation Panel populations, providing a vast public resource of genotype and gene expression data.

6.2.4.1 CEPH Collections

The CEPH LCLs (http://www.cephb.fr) consists of 1064 LCLs from 1050 individuals in 51 world populations, including 30 trios from the international HapMap CEU samples (northern and western European ancestry from Utah). Most CEPH LCLs were derived from Caucasian individuals of European multigenerational families, representing general, but not disease-targeted, populations. Since the article by Cann et al. [39] on the HGDP-CEP Human Genome Diversity Cell Line Panel, three standardized subsets of the original diversity panel have been recommended for future population genetic studies [40]. For example, the first subset (denoted H1048) contains 1048 samples of the original HGDP-CEPH panel, excluding one member of each duplicate pair and two individuals with extremely atypical genotypes for their population. The second subset (denoted H971) excludes 77 individuals from the H1048 in order to avoid including two individuals with a first-degree relationship (parent/offspring or full sibling). The third subset (denoted H952) excludes additional 19 individuals from the subset H971 so that the H952 contains no two individuals with a second-degree relationship (half-sibling, avuncular, or grandparent/grandchild).

The CEPH LCLs have been extensively genotyped for genetic variants such as SNPs and CNVs; these data are publicly available (http://snpdata.cshl.edu/population_studies/linkage_maps//). Most importantly, CEPH cell panels provide publicly available baseline gene expression data of the families, as in the Gene Expression Omnibus of CEPH pedigrees (http://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE1485) and CEU RNA-Seq data (http://jungle.unige.ch/rnaseq_CEU60). These CEPH LCLs can be obtained from the CEPH collection through the Coriell Institute for Medical Research (http://locus.umdnj.edu/nigms/ceph/ceph.html).

6.2.4.2 HapMap Collections

The International HapMap LCL collections are one of the most studied LCL collections (http://www.hapmap.org). The HapMap Phase I/II comprises 270 LCL cell lines from Caucasian groups (CEU) plus three different ethnic groups (YRI, Yoruban people in Ibadan, Nigeria; CHB, Han Chinese in Beijing; JPN, Japanese in Tokyo). These LCL panels were derived from 30 CEPH trios from the Caucasian CEU population, 30 trios from the Nigerian YRI population, 45 unrelated people from the Han Chinese CHB population, and 45 unrelated people from the Japanese JPT population. For the HapMap Phase III project, an additional 1031 LCL cell lines were derived from seven other populations (ASW, people of African ancestry in the Southwestern U.S.; GIH, Gujarati Indians in Houston, Texas; LWK, Luhya people in Webuye, Kenya; MEX, people of Mexican ancestry in Los Angeles, California; CHD, Chinese in Metropolitan Denver, Colorado; MKK, Maasai in Kinyawa, Kenya; and TSI, Toscani in Italy) [41]. These International HapMap LCLs cells are also available from the Coriell Institute for Medical Research (http://ccr.coriell.org).

6.2.4.3 NBK Collections

In the last decade, a large number of biobanks have been established to study human genome diversity and gene–environment interaction in the context of personalized medicine. These biobanks have collected various human biological samples, including blood-derived and urine samples. Some biobanks, like the U.K. Biobank, store blood-derived cell samples (e.g., whole blood, buffy coats, or peripheral blood mononuclear cells) for future applications (e.g., LCL generation). In contrast, the National Biobank of Korea (NBK), which is Korea's biggest population-based biobank, separated peripheral blood mononuclear cells from ACD-mediated anti-coagulated whole blood and subsequently conducted EBV transformation in the presence of cyclosporine A. The NBK is responsible for biobanking of biological samples from various population-based cohort studies for the Korean Genome and Epidemiology Study (KoGES); for further information, see http://www.nih.go.kr/NIH/eng/contents/NihEngContentView.jsp?cid=19822&menuIds=HOME004-MNU0710-MNU1028-MNU1029.

So far, the NBK has established large-scale LCL collections of approximately 15,000 LCLs from various cohort studies (http://kbn.cdc.go.kr). These collections comprise about 11,000 LCLs derived from community-based urban and rural cohort participants, about 2500 LCLs from twin cohort participants, and about 1500 LCLs from elderly cohort participants. Among these NBK LCLs, the Korean HapMap LCLs were derived from 90 unrelated healthy Korean individuals of an equal sex ratio and age (40–69 years at the time of baseline study).

Among the Korean HapMap LCLs, 20 LCL strains were randomly selected for study of their biological characteristics and genomic changes during LCL generation and maintenance [42]. This special collection comprised 17 immortal LCL strains that were able to proliferate more than the passage number of 160 (p160) during continuous long-term subculture, and three nonimmortal LCL strains that stopped proliferation around the passage number 40 (p40), at which point LCLs undergo cellular crisis. Most of the NBK LCL samples are linkable to health information as well as to biological samples (e.g., peripheral-blood DNA, serum, plasma, urine) from the same donors. Moreover, some donors have been genotyped for genetic variations (e.g., SNPs, CNVs) in genome-wide association studies. A large collection of NBK LCLs will provide a good resource for genome-wide expression studies as well as pharmacogenomic discovery science, which requires a sufficient sample size to represent ethnic diversity.

6.2.4.4 NLGIP Collections

The National Laboratory for the Genetics of Israeli Populations (NLGIP) provides research communities with 1673 LCLs from various Jewish and Arab populations in Israel (http://www.tau.ac.il/medicine/NLGIP/catalog.htm). All NLGIP donors were over 18 years old and Israeli citizens. LCL cells and matching DNA samples from the NLGIP have been used to study the polymorphism of drug-metabolizing enzymes in Israeli populations, including CYP2C9, CYP2C19, and CYP2D6. Recently, these NLGIP LCLs were extensively utilized in pharmacogenomic studies of LCL gene expression profiles.

6.2.4.5 Other LCL Collections

Many LCL collections can be found in the PubMed literature and websites. The MACS (Multicenter AIDS Cohort Study) holds EBV-transformed B-cell lines and PBMC pellets in addition to plasma and serum samples from over 7000 participants (http://www.statepi.jhsph.edu/macs/macs.html). MACS is an ongoing prospective study of the natural and treated histories of HIV-1 infection in homosexual and bisexual men, conducted at study sites located in multicenters in Baltimore, Chicago, Pittsburgh, and Los Angeles [43,44].

The International Histocompatibility Working Group (IHWG) also provides a comprehensive LCL inventory which is maintained by the Research Cell Bank (RCB) located at Fred Hutchinson Cancer Research Center (http://www.ihwg.org/). The core inventory consists of more than 1000 cell lines from the tenth, twelfth, and thirteenth IHWS, from HLA heterozygous and homozygous donors, from selected families, and from individuals of diverse population groups. It maintains stocks of purified DNA from LCLs and DNA reference panels that provide an extensive array of HLA and HLA-related genetic variants. Collectively, these cell lines represent more than 375 unique HLA-A, B, C, DRB1, DQA1, DQB1, DPA1, and DPB1 alleles.

The Avon Longitudinal Study of Parents and Children (ALSPC) is a long-term health research project also known as Children of the 90s (http://www.alspac.bris.ac.uk). It enrolled more than 14,000 mothers during pregnancy in 1991 and 1992, and has followed the health and development of their children over two decades. Biological samples, including blood, urine, hair, nails, saliva, and placenta, have been collected from children and their parents since early pregnancy. Until now, approximately 15,000 LCLs have been generated from children (n>7100), mothers (n>5700), and partners (n>1900). In addition, approximately 22,000 samples of genomic DNA from blood, LCLs, and mouthwash samples can be provided for research projects as outlined in ALSPAC policy. ALSPAC provides a rich resource for the study of the environmental and genetic factors that affect health and development. Thus it aims to inform policy and practices that will provide a better life for future generations.

The Cedars-Sinai Medical Center published its prolonged experiences of EBV B-cell transformation in 1991. They established about 2900 LCLs by EBV transformation, about 600 of which were from frozen lymphocytes. Success rates using freshly isolated versus previously frozen lymphocytes are approximately 97% [26].

6.3 BIOLOGICAL CHARACTERISTICS OF LCLs

The following subsections discuss the effects of EBV transformation and long-term subculture on biological characteristics of LCLs.

6.3.1 EBV Transformation Effects on B Cells

In general, EBV-transformed B lymphocytes are highly variable in shape and tend to make cell clumps in stationary cultures [45]. However, cell clustering is not a specific indicator of EBV-mediated growth transformation. Ficoll/Hypaque-gradient centrifugation is used to separate the interface containing peripheral mononuclear cells from the pellet and lower gradients containing the majority of red cells and mature granulocytes. Generally EBV-transformed B lymphocytes grow in suspension with immunoglobulin synthesis, but EBV infection of B lymphocytes occasionally generates unusual lymphoblastoid cell lines that grow uniform and round with no detectable synthesis of immunoglobulin and lysozyme [45].

EBV infection mimics the effect of B-cell activation signals such that EBV-infected B cells exhibit higher proliferation activity than resting B cells [46]. The B-cell activation method was applied to shorten the time required for EBV-mediated B-cell transformation. For example, Hur et al. [47] reported that EBV-infected B cells were activated to accelerate the cellular transformation process when treated with anti-human CD19 and anti-human IgM monoclonal antibodies. Generally, the transformation takes about 4 weeks, and cell clumps of increased cell size can be seen at 1–3 weeks after EBV infection. This CD19-immunoglogulin co-ligation method was able to synergistically shorten the time for generating LCLs without changes in typical phenotypes of EBV transformation such as cell surface molecule expression, which accelerates cell clump formation within at least 14 days. On the other hand, Oh et al. [48] reported that the use of EBV viral stocks prepared from TPA-activated B95-8 cells not only shortened the time of LCL generation but also increased the success rate of immortalization.

6.3.1.1 Immunophenotypes

EBV-transformed B cells have been found to be mainly positive for CD38 (like germinal center B cells). IgD and CD38 cell surface molecules have been widely used for B-cell phenotyping in association with B-cell development. EBV-infected B cells undergo changes in immunophenotypes of IgD and CD38 cell surface molecules. That is, the resting B cells represent the IgD(+)CD38(−) cells, while the EBV-infected B cells represent the IgD(−)CD38(+) cells. This is similar to the germinal center B-cell phenotype. On the other hand, colligation of the membrane protein CD19 with the antigen receptor of B lymphocytes decreases the threshold for antigen receptor–dependent stimulation so that the B cell can be activated in response to low concentrations of antigens [49].

In early cellular events of EBV infection, two distinct subpopulations of CD23(+) B cells exhibit different destinations for proliferation of EBV-infected B cells. Indeed, in one study the expression pattern $CD23^{hi}CD58(+)IL6(-)$

predicted the identity of infected cells destined for proliferation as early as three days after exposure to EBV. In contrast, another subpopulation marked with CD24^{lo}CD58(+) IL(+) failed to proliferate despite the fact that LMP1 and EBNA2 were expressed in individual CD23hiCD58+ and CD23loCD58(+) cells, demonstrating that reduced levels of LMP1 do not explain the lack of CD23loCD58(+) cell proliferation. This result suggests that B-cell subpopulations are differentially susceptible to EBV-mediated proliferation [30].

6.3.1.2 Gene Expression Changes

Microarray analyses of 10 LCLs and corresponding donors' B cells reveal that EBV-infected B cells exhibit gene expression changes involved in cell proliferation, cell cycle, and immune response, compared to resting B cells [7]. Specifically, 232 genes, including *STMN1*, *RAB9*, *RAB27A*, and *MYBL2* were found to be upregulated in LCLs compared to resting B cells, while 111 genes, including *BACH1*, *BACH2*, *RAB37*, *JUNB*, and *VAV3* were downregulated in LCLs. Resting B cells represented mostly cell cycle–arrested cells in the G0 + G1 phases, while EBV-infected B cells exhibited more proliferating cells in the S and G2 + M phases. Thus, differentially expressed genes between resting and EBV-infected B cells may explain changes in cell cycle profiles in the EBV-infected B-cell transformation.

6.3.2 Long-Term Subculture Effects on LCLs

6.3.2.1 Growth Properties

Once EBV-transformed B cells overcome a proliferative cellular crisis in a middle passage number (around 40), they become capable of continuously proliferating up to a passage number of 160–180, at which point the LCLs are considered to be terminally immortalized [50]. Many studies support biological differences between LCLs at early passages after EBV infection and LCLs at late passages after long-term subculture. To some extent, it is convenient to conceptually discriminate the early LCLs (eLCLs) at a passage number approximately less than 30–40 from terminally immortalized LCLs (tLCLs) at a passage number of more than 160. It is known that the cellular immortalization of LCLs is affected by many factors, including culture conditions, EBV viral activities, and host genomic backgrounds.

In our hands, most of LCL strains (17 out of 20) could proliferate up to a passage number of 160 (p160) in the continuous long-term subculture in which culture medium was exchanged with fresh complete medium at every passage. The remaining three LCL strains stopped proliferation around an average passage number of 41. These nonimmortal LCLs exhibited relatively lower copy numbers of mitochondrial DNA and EBV genome than terminally immortalized LCLs, suggesting that reduced mitochondrial activity may be indicative of diminished EBV-mediated proliferative activity. Thus, in order for LCLs to be immortalized and maintained during long-term subculture, they require sustained EBV viral activities, including EBV viral gene expression and viral genome copy numbers as well as telomerase activity [51,52].

6.3.2.2 Gene Expression Phenotypes

Long-term LCL subculture–induced gene expression changes in NF-kB pathway- and carcinogenesis-related genes that may be involved in the completion of cellular immortalization and EBV-induced tumorigenesis [53]. Indeed, microarray analysis showed that approximately 500–1500 genes per LCL strain were differentially expressed between eLCLs and tLCLs. Of these differentially expressed genes, *CD38* and *PTPN13* were downregulated and upregulated in tLCLs, respectively, compared to eLCLs among all tested 17 LCL strains.

By contrast, 13 genes (*CD180*, *FCRL5*, *GPR160*, *HERC5*, *IFIT1*, *OAS3*, *RASGRP3*, *RFTS7H*, *TC2N*, *TCL1A*, *XAF1*, *ZNF382*- and miR-146a) were downregulated in 16 tLCLs out of 17 tested LCL strains, while *PRKCH* was upregulated in 16 tLCLs. It is known that *PTPN13*, *HERC5*, and miR-146a are associated with NF-kB pathway while *XAF1*, *TCL1A*, and *CD38* are associated with carcinogenesis. In addition, miR-146a is upregulated by LMP1 via NF-kB in lymphocytes. Thus, the NF-kB pathway plays an important role in prolonged LCL subculture. Differentially expressed genes between eLCLs and tLCLs would provide not only molecular signatures required for LCL immortalization but also potential quality control markers related to LCL passage numbers during long-term subculture.

6.3.2.3 miRNA Expression Phenotypes

It is known that miRNAs regulate the expression of their target genes at the levels of transcription and translation, contributing to global gene expression regulatory machineries in cell proliferation, differentiation, and apoptosis. To extend LCL applications to studies using miRNA, it is necessary to understand changes in miRNA expression profiles between eLCLs and tLCLs during LCL generation and maintenance. Using long-term subculture collections of 17 matched pairs of early- and late-passage LCLs, miRNA microarray analysis showed that 46–133 miRNAs per LCL strain were differentially expressed with more than a two-fold change between eLCLs and tLCLs [54]. In particular, miR-99a, miR-125b, and miR-1296 were upregulated in tLCLs compared to eLCLs, while miR-20b*, miR-28-5p, miR-151-3p, miR-151:9.1, miR-216a, and miR-223* were downregulated in tLCLs. In addition, these miRNA expression profiles were able to discriminate eLCLs from tLCLs, as determined by hierarchical clustering analysis.

Interestingly, when target genes of such differentially expressed miRNAs were putatively predicted by miRNA target prediction tools (e.g., TargetScan and miRDB), the corresponding target genes were found to coincide with differentially expressed genes between eLCLs and tLCLs. For example, *CD38*, *FCRL5*, and *XAF1* were target genes of miR-28-5p while *RASGRP3* and *GPR160* were target genes of miR-99a and miR-125b, respectively. These target genes and miRNAs also exhibited negative correlation of expression patterns, which suggests that these pairs of miRNAs and target genes may play roles in LCL maintenance and cellular immortalization. The differentially expressed miRNAs would provide miRNA signatures associated with terminal immortalization of LCLs rather than the initial stage of EBV-mediated B-cell transformation, and could be a potential marker for cellular immortalization and quality control of long-term culture collections of LCLs.

6.4 POTENTIALS AND LIMITATIONS OF LCL APPLICATIONS

It is important for LCL applications in genetic, pharmacogenomic, and immunological studies to know how well LCLs preserve the genetic information and biological characteristics of primary B cells during LCL generation and maintenance. For this reason, various studies have been conducted to evaluate biological and genomic characteristics of LCLs compared to primary B cells. For example, one recent study showed that gene expression profiles and promoter-methylation profiles were affected by EBV transformation while interindividual variations in gene expression levels of the primary B cells were maintained in the LCLs [55]. Here, the uses and applications of LCLs are exemplified to discuss the potential and the limitations of such applications.

6.4.1 Genomic Studies Using LCLs

6.4.1.1 SNPs

The feasibility of using LCL in genetic studies has been extensively evaluated for genomic structural variations, SNP analysis, expression phenotype studies, and the like. The Multicenter AIDS Cohort Study (MACS) studied fidelity of SNP genotype calls in DNA samples that were obtained from paired samples of PBMCs and LCLs from 16 individuals of European American ancestry. They showed that genotypic fidelity increased with more stringent SNP calling quality control. For example, the average mismatch rate was 0.12% for SNPs with a population call rate of at least 95%, and 0.03% for SNPs with a call rate of at least 99%. This work indicated that genotypic discrepancies found in PBMC and LCL pairs were likely to have no apparent gross genotypic errors in the process of EBV transformation, suggesting that mismatch rates of SNP genotypes are minimal with stringent quality control [43].

In addition, SNP fidelity was estimated on the long-term subculture panel of the NKB LCL collection between early and late passage of LCLs during long-term subculture [56]. Genotype calls from the Affymetrix 500K SNP array set were used to estimate genotype concordance between PBMCs and LCLs using identify-by-state (IBS) analysis. The mean pairwise IBS distance of original SNPs was approximately 0.995 between PBMCs and different passage numbers of LCLs, indicating that LCL DNA is a reliable source for genotyping with SNP chip platforms.

However, loss of heterozygosity (LOH) was observed on the loci showing the highest rates of genotype discordance with PBMCs; such LOH abundance increased with higher passage numbers of LCLs. This result suggests that LOH may be a major cause of genotype errors for late-passage LCLs. Substantial genotypic errors were observed mostly in late-passage LCLs (tLCLs), but not in early-passage LCLs (eLCLs, <40 passages). Indeed, overall mean genotype concordance between PBMCs and LCLs was 0.996 for the SNPs that are most frequently used in GWAS. It is therefore likely that LCLs are a reliable DNA source for genetic studies if the DNA sample is harvested from the early-passage LCLs.

Recently, NGS technology was used to study genomic differences between blood and LCL DNA. Londin et al. [31] reported that, on whole-exome sequencing of a tetrad family, an average of 19,354 genetic variants (17,672 SNPs and 1682 indels) were identified per sample in the coding sequences of peripheral-blood mononuclear cells and LCLs from the same donor. They found approximately 99.82% concordance in DNA sequences between PBMCs and LCLs, leaving a de novo mutation rate of 0.18%. Study findings suggest that LCLs are an appropriate representation of the genetic material of the donor but the researchers recommend that PBMC or early-passage LCLs be used.

Linkage analysis using family-based data cannot be applied to infectious diseases such as in susceptibility studies because of the rarity of multi-case family diseases such as HIV infection and tuberculosis. However, the use of an *in vitro* novel strategy based on HIV infection of LCLs successfully identified new genetic variants that influence susceptibility to HIV-1 [57]. The conditions for efficient transduction of LCLs with a VSV.G (vesicular stomatitis virus G protein) -pseudotyped HIV-1-based vector that expresses the GFP reporter gene in transduced LCLs was established. Interestingly, the researchers observed a significant correlation (Pearson $R^2 = 0.56$, $p = 0.007$) between the levels of transduction of CD4+ T cells and LCLs for the same donors, suggesting that LCLs reflect CD4+ T cell behavior. Through a quantitative genome-wide linkage analysis, a region on HSA8q24.3 (marker rs1398296) was identified as the genomic locus contributing the variation in cellular susceptibility to HIV. This genetic variant was also associated with accelerated disease progression in one of two cohorts of HIV-1-infected patients. This suggests that genetic analysis of *in vitro* cellular phenotypes would facilitate the discovery of susceptibility loci to infectious agents.

6.4.1.2 CNVs

In many studies, the genome-wide SNP assay has been used for analyses of copy number variations in LCLs. In one study, for example, a HapMap collection (n = 270 LCLs) was used to generate the comprehensive genome-wide map of copy number of variations (CNVs) in the human genome. This study exploited two technology platforms of the Affymetrix GeneChip Human Mapping 500K array and the CGH Whole Genome TilePath array to generate CNV information from the HapMap collection, consisting of 30 parent-offspring trios of the Yoruba from Nigeria (YRI), 30 parent-offspring trios of European descent from Utah (CEU), 45 unrelated Japanese from Tokyo (JPT), and 45 unrelated Han Chinese from Beijing (CHB). A total of 1447 copy number variable regions (CNVRs) covering 360 megabases—912% of the genome) were identified in diverse populations. Moreover, it was estimated that LCL-specific genomic errors accounted for less than 0.5% of observed copy number variations (CNVs), implying that LCLs are robust sources of genomic DNA for CNV studies [58].

Simon-Sanchez et al. [59] used LCL DNA for a genome-wide SNP assay conducted to detect structural genomic variations in LCLs (n = 270) from neurologically normal healthy donors. They assayed 408,804 SNPs for genotyping using the Infinium Human-1 Genotyping BeadChip (containing 109,365 gene-centric SNPs) and the HumanHap300 Genotyping BeadChip (containing 317,511 SNPs) with 18,072 SNPs in common between the two arrays. The researchers observed extended homozygosity (contiguous tracts >5 Mb) in 9.5% (26/272) of LCLs and 340 structural genomic alterations in 66.9% (182/272) of LCLs. Such structural genomic variations were confirmed in further examination of DNA extracted directly from the blood of 30 of these subjects. This study showed that LCLs have few or only minor effects on genomic structural variation and are unlikely to confound the results of a genome-wide case-control study.

On the other hand, a recent study using LCLs showed the successful discovery of copy number variations by analyzing genome-wide SNP chip data [60]. In initial screening steps, Jeon et al. used SNP array data from the Affymetrix 50K SNP array and the Affymetrix SNP 5.0 array for the Korean HapMap LCLs (n = 90), and then validated CNV regions by quantitative multiplex PCR of short fluorescent fragment (QMPSF). This approach enabled identification of DNA copy number variations at the LEPR gene locus encoding the first two exons of *LEPR* and *LEPROT* genes in LCLs from the Korean population. In addition, this work revealed an association between a structural variation at the LEPR gene locus and complex metabolic traits and the risk of type 2 diabetes.

A recent study reported results of an analysis of the whole-genome sequencing data (40X) for a pair of LCLs and whole blood from the same donor [61]. It determined with high confidence that 99.2% of the genome were identical with no reproducible changes in indels or structural variations, including chromosomal rearrangements and copy number variations. Specifically, when inspected ploidy from genome coverage files in windows of 2kb, the LCL exhibited a decreased copy number in only 4 regions (3 haploid regions, 1 deletion) that contain 4 genes (*KIAA0125*, *PRAME*, *ZNF280A*, *ZNF280B*) and 1 pseudogene (*ADAM6*), compared to the genomic DNA from PBMCs.

6.4.1.3 LCL Transcriptomics

Several gene expression studies showed that LCLs can be used as a potential source of a molecular screen for diseases or environmental stresses. For example, DNA microarray analyses of 116 LCLs from individuals with idiopathic autism identified circadian rhythm–related genes that are differentially expressed in the most severely affected ASD group, providing a clue to circadian rhythm dysfunction in severe autism [62].

On the other hand, another study analyzed transcriptomic profiles of LCLs to identify irradiation-responsive genes and characterize their temporal expression profiles. In this study, CEPH LCLs from 10 unrelated individuals were irradiated at 2 different doses, 3 Gy and 10 Gy, and then harvested at various time points, 0, 1, 2, 6, 12, and 24 hr, after irradiation exposure before pooled RNA samples from all 10 individuals were used for microarray experiments. This genome-wide transcriptional survey of irradiated LCLs demonstrated that LCLs are a very useful model in elucidating the complex transcriptional processes involved in response to DNA damage following irradiation exposure [63].

LCL expression phenotypes (transcript expression levels) can be used to identify potential target genes associated with clinical traits. Correlation studies were conducted to show the utility of LCL expression phenotypes in association studies. Indeed, clinical trait–associated genes were identified from regression analysis using eLCL expression phenotypes and quantitative clinical data from the corresponding donors. For example, gene expression levels of *APOC1* or *NAT12* in eLCLs were significantly associated with 120 min postprandial glucose level in corresponding donors with the positive or negative relationship, respectively, while body mass index (BMI) was positively or negatively correlated to *SERPINB12* or *ACP2*, respectively. Among these significant correlations, the three highest coefficients of determination (R^2) were observed in correlations between CRP (C-reactive protein) levels and *TMSL8* ($R^2 = 0.798$), between BMI and *SERPINB12* ($R^2 = 0.722$), and between 120 min postprandial insulin levels and *ERRF11* ($R^2 = 0.713$). These clinical trait–associated expression phenotypes will facilitate the discovery of novel candidate target genes of diseases or clinical symptoms. For example, it is possible that *APOC1* and *SERPINB12* may be candidate target genes for diabetes and obesity.

However, correlations of expression phenotypes with clinical traits in eLCLs were not replicated in tLCLs, suggesting that the utilization of expression phenotypes should consider LCL passage numbers. Indeed, differential cytotoxicity of anti-cancer agents was observed in pre- and postimmortal LCLs [64]. The postimmortal LCLs undergo cellular immortalization processes such as overcoming the proliferation crisis, increased telomerase activity, abnormal karyotypes, p53 mutation, and downregulation of p16/Rb, mimicking lymphoma cells.

In contrast, the preimmortal LCLs have normal diploid karyotypes and undergo telomere shortening, representing characteristics of actively proliferating normal lymphoblasts. Cytotoxicity tests using pre- and postimmortal LCLs showed that the postimmortal LCLs were significantly more resistant to cytotoxicity of DNA-modifying agents (e.g., camptothecin, etoposide, bleomycin, fluorouracil, thioguanine, melphalan, actinomycin D) while pre- and postimmortal LCLs showed similar levels of cytotoxicity against DNA-nonmodifying agents (colchicines, paclitaxel, vincristine, methotrexate). This result suggests that pairs of pre- and postimmortal LCLs provide a good model for assessing and screening anticancer drugs. That is, if a certain chemical exhibits stronger cytotoxicity in preimmortal LCLs, it is possibly a DNA-modifying agent and may have stronger adverse effects on actively proliferating normal cells. In contrast, if an agent has a markedly stronger cytotoxicity in postimmortal LCLs, it is possibly an ideal anticancer drug because it possibly has weaker side effects on actively proliferating normal cells.

6.4.1.4 *Expression Phenotype Studies (eQTL)*

In contrast to CNV and SNP, the utility of mRNA expression of LCLs is controversial for eQTL analysis. Choy et al. showed that nongenetic factors, such as EBV genome copy number, *in vitro* growth rate, and cellular ATP levels of individual LCLs, were more strongly associated with drug response and mRNA expression phenotypes than genetic factors, such as genotypic variation. Some reports have suggested that LCL mRNA expression data may not be suitable for eQTL studies because of random sampling of LCL clones with monoallelic expression [65,66].

6.4.1.5 *Protein*

Wu et al. [67], in a recent study, showed that protein levels of LCLs are heritable molecular phenotypes that exhibit considerable variation between individuals, populations, and sexes. They used isobaric tag–based quantitative mass spectrometry to determine relative protein levels of 5953 genes in lymphoblastoid cell lines from 95 diverse individuals genotyped in the HapMap project. They also identified protein quantitative trait loci (pQTLs), including variants not detected by previous transcriptome studies. Recently, a protein expression study using LCLs identified the differential expression of DNA repair and cell apoptosis–related proteins, including *RPA32* and p27 in response to radiofrequency radiation [68]. LCL proteomics have been also conducted to discover biomarkers of diseases, including bipolar disorder [69].

6.4.1.6 *DNA Methylation*

DNA methylation is an essential epigenetic mechanism that modulates gene expression and the maintenance of DNA integrity and stability. In order to find genetic variants of dopamine receptor D4 gene (*DRD4*) associated with DNA methylation levels, DNA methylation profiles of 89 LCLs from individuals (from 30 family trios) were interrogated for associations with *cis*-acting genetic variants within the promoter region of dopamine receptor D4 gene [70]. These associations between DNA methylation levels and genetic variants in LCLs were nominally replicated in the postmortem brain tissue that is the *DRD4* target tissue implicated in psychiatric disease phenotypes. This association study provided an alternative approach to assigning a possible functional role to seemingly nonfunctional SNP associations. Recently, Bell et al. [71] reported genome-wide associations between DNA methylation levels with genetic variants and gene expression variations using 77 LCLs from HapMap Yoruba individuals. DNA methylation patterns were used for association analyses with genetic and gene expression variations in LCLs.

6.4.1.7 *RNA-seq*

With the advent of next-generation sequencing (NGS), RNA-seq data have been produced from different sets of LCL panels, including 20 European-ancestry individuals from the Utah pedigrees of Coriell CEPH cell lines [72]; (http://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE29158), 60 LCLs from CEU individuals (CEPH Europeans from Utah) with the Illumina GAII platform [73], and 69 Yoruban individuals (African descent) with the Illumina GAII platform [74]. The RNA-seq analysis of the Utah LCLs detected most of the known genes because only 21 alternatively spliced, multi-exon genes that are not in databases were uncovered at about 40 million sequence reads per sample [72]. In early 2013, RNA-seq data from 1000 genome samples were released. This RNA sequencing dataset of 462 human lymphoblastoid cell line samples from the CEU, FIN, GBR, TSI, and YRI populations from the 1000 Genomes sample collection was created by the Geuvadis consortium (http://www.geuvadis.org/web/geuvadis/home).

6.4.1.8 miRNA

EBV was the first virus found to encode miRNAs. During EBV transformation and cellular immortalization, EBV-infected cells express not only host cellular miRNAs (e.g., miR-155, miR-146a/b, miR-21, miR-103, miR-320a/b/c/d, let-7(a-i)) which account for about 50% of all miRNAs, but also EBV-encoded miRNAs (e.g., miR-BART1-5p/3-5p/4-5p, miR-BHRF1-1/1-2-3p/2-5p), which account for 7–22% of the total miRNAs expressed in LCLs [75]. These host and viral miRNAs are involved in the immune and apoptotic response for establishing a latent infection, ultimately contributing to viral oncogenesis. For example, miRNA-155 was dramatically upregulated by EBV latent membrane protein 1 at the initial stage of EBV infection. In contrast, miRNA-155 was not differentially expressed between early-passage LCLs (eLCLs) and terminally immortalized LCLs (tLCLs) of passage number p160, suggesting that miRNA-155 is required to be sustained for LCL maintenance during long-term subculture.

Recent reports showed the possibility that transcriptomic miRNA profiles of LCLs could be utilized as expression phenotypes for association studies with clinical traits or disease conditions. In the association study using miRNA expression profiles of 20 LCLs and their donors' clinical information, it was observed that expression levels of miR-188-3p and miR-296-3p were significantly associated with systolic blood pressure ($R^2 = 0.202$, $p = 0.047$) and HbA1C levels ($R^2 = 0.272$, $p = 0.018$), respectively. These clinical trait–associated miRNAs (e.g., miRNA-188-3p, miRNA-296-3p) may be new molecular candidate targets for studies of clinical trait–related diseases such as metabolic syndromes and diabetes.

6.4.2 Pharmacogenomic Studies Using LCLs

Many studies have been conducted to discover the relationship of drug sensitivity with genetic variants and global gene expression in LCLs (Figure 6.2). The cytotoxicity assays of LCLs represent a good *in vitro* model for finding genetic variants and target genes associated with drug responses

FIGURE 6.2 **Applications of LCL-based assays in pharmacogenomic studies.**

in pharmacogenomic research. Most genome-wide association studies employing expression phenotypes of LCLs have used simple association methods using dose-response phenotypes of individual LCLs, where dose—response curves are necessarily nonlinear. Furthermore, many pharmacogenomic studies assume that drug response is a heritable trait, and that differential drug response is defined by one parameter of a complex nonlinear model.

In most pharmacogenomic studies, cell growth inhibition was evaluated for each cell line at different concentrations of a given drug by measuring the concentration required to inhibit 50% cell growth (IC_{50}). Such IC_{50} values of given drugs are first determined for individual LCLs and then used as variables of cellular phenotypes presumably inherent in individual LCLs in association studies. In contrast, the cell proliferation activity of drug-treated cells can also be used as cellular phenotypes for association studies. This method is based on the activity of mitochondrial enzymes that are inactivated shortly after cell death and therefore reflect the number of viable cells after drug exposures.

Cell growth activity is measured either by directly counting viable cells after drug treatment at a certain concentration or by using the colorimetric 2,3-bis(2-methoxy-4-nitro-5-sulfophenyl)-5-([phenylamino] carbony)-2H-tetrazolium hydroxide (XTT) assay in the cell lines treated at drug concentrations for inhibiting 50% of cell growth (IC_{50}). Therefore, either IC_{50} values of drugs for individual LCLs or cell proliferation activity (direct XTT measurements) of drug-treated LCLs can be exploited in association studies such as triangle association and case control, as discussed next.

6.4.2.1 *Triangle Association Model*

In pharmacogenomic studies utilizing LCLs, the most common approach is based on the triangle model that integrates genotype (SNPs), gene expression (transcription profiles), and *in vitro* cytotoxicity (drug responses) data from LCLs. Many genetic components related to drug responses were discovered via the triangle model or the genome-wide genetics of gene expression using LCLs, although such association methods still need to be improved. For example, a recent whole-genome study utilized genotype data and baseline gene expression data of LCLs from three different ethnic populations (CEU/HAPMAPPT01, n = 78; YRI/HAPMAPPT03, n = 87; ASW/HAPMAPPT07, n = 90), where a general linear regression analysis allowed identification of solute carrier transporter (SLC) genes (*SLC31A2*, *SLC43A1*, *SLC35A5* and *SLC41A2*) associated with paclitaxel sensitivity [76].

In addition, eQTLs regulating SLC gene expression were identified using the SCAN database (http://www.scandb.org), and all SNPs were found to be trans-acting eQTLs of their respective SLC gene. That is, rs6935238 was significantly associated both with the baseline gene expression of *SCL31A2* ($P = 8 \times 10 - 5$) and with paclitaxel-induced cytotoxicity in three populations ($P = 1.5 \times 10 - 6$). One eQTL (rs13419945) was significantly associated with cytotoxicity ($P = 4.6 \times 10 - 5$) and baseline gene expression of both *SCL35A5* and *SLC41A2* in LCLs. In these association studies, the use of well-genotyped LCL panels such as the international HapMap take advantage of accumulated genomic data from ethnically diverse populations.

The triangle model has also been used successfully to identify pharmacogenomic candidates associated with the response to many chemotherapeutic agents, including carboplatin [77], gemcitabine and arabinosylcytosin [78], cytarabine arabinoside [79], and tamoxifen [80]. The triangle model has also been applied to radiation pharmacogenomics studies in which integrated analysis was performed with SNPs, basal gene expression, and radiation sensitivity. It is known that genetic inheritance plays an important role in individual variations in radiation response.

Indeed, it was estimated that genetic factors might account for nearly 80% of interindividual radiation response variations. Moreover, peripheral blood lymphocyte radiosensitivity is known to be significantly correlated with clinical response or radiation morbidity. In general, radiation pharmacogenomics studies have identified target genes that might contribute to interindividual variations in radiation response, utilizing genome-wide basal gene expression profiles, genome-wide SNPs, and radiation cytotoxicity obtained from hundreds of irradiated LCLs.

Recently, a radiation cytotoxicity study used the radiation AUC (area under the curve) as an *in vitro* radiation response phenotype from 277 LCLs, including 93 African American (HD100AA), 89 Caucasian American (HD100CAU), and 95 Han-Chinese American (HD100CHI) unrelated healthy subjects [81]. Radiation cytotoxicity differed significantly among the three racial groups. LCLs from Han-Chinese American subjects were more sensitive to radiation than LCLs from Caucasian American subjects. Such radiation AUC for 277 LCLs was used in correlation analysis for the association of genome-wide SNPs and basal expression with radiation cytotoxicity. Subsequent functional validation using siRNA knockdown showed that *C13orf34*, *MAD2L1*, *PLK4*, *TPD52*, and *DEPDC1B* significantly altered radiation sensitivity in cancer cell lines, implying that these genes might be novel biomarkers contributing variations in response to radiation therapy.

6.4.2.2 *Case-Control Design*

The NLGIP LCLs from healthy adult females (n = 80) were phenotyped for drug sensitivity in response to paroxetin, a selective serotonin reuptake inhibitor (SSRI) at a concentration of 10 uM, which represents the mean IC_{50} for growth inhibition [82]. Based on paroxetin sensitivity, 14 "outlier" LCLs were selected for gene expression profiling, which included the most sensitive LCLs (n = 7) and the least sensitive group (n = 7). Of the differentially expressed genes between the two outlier LCL groups (e.g., *ARRB1*, *CCL5*, *DDX60*, *DDX60L*, *ENDOD1*, *ENPP2*, *FLT1*, *GABRA4*, *GAP43*, *MCTP2*, *SPRY2*), the most striking differential gene expression was observed for *CHL1* (cell adhesion molecule with homology to *L1CAM*), which is known to be implicated in correct thalamocortical circuitry, schizophrenia, and autism. This result suggests that these differentially expressed genes, including *CHL1*, may be a promising candidate SSRI response biomarker and that *CHL1* protein may have potential as an antidepressant drug target. This indicates that similar approaches using *in vitro* drug response phenotypes and LCL gene expression profiles can provide a tool to discover drug pathways and drug response–related biomarkers.

In a study [83] undertaken to discover genomic predictors of interindividual sensitivity to a DNA alkylating agent (MNNG), a panel of 24 LCLs was divided into two classes with either high or low sensitivity for a two-class prediction algorithm. Of these cell lines, the four most sensitive and the four least sensitive LCL strains were selected and analyzed to identify differentially expressed genes with significant positive or negative correlation with increasing MNNG sensitivity. They found that increased *MYH* or decreased *C21ORF56* gene expression was correlated with increased alkylating sensitivity, implying that a collective set of another 48 genes, including *MYH* and *C21ORF56*, may be used as predictors of cellular sensitivities to chemotherapeutics. Therefore, a panel of LCLs can be classified into case-control groups based on cellular responses to drugs or environmental toxicants in order to discover genomic predictors or modulators of cellular sensitivities to drugs or compounds.

6.4.2.3 *Clinical Translation of LCL Findings*

Increasing numbers of *in vitro* cell-based pharmacogenomic findings have been successfully replicated in clinical settings. That is, genetic variants identified in the LCL-based model could be used in identifying patients treated with carboplatin with clinical outcome. For example, a recent study demonstrated that LCL-based genome-wide approaches identified carboplatin sensitivity–associated genetic variants that were successfully validated in clinical samples from patients treated with carboplatin [84]. In this genome-wide approach, HapMap LCLs (HAPMAPPT01, CEU, n = 87, for the discovery set) and 52 unrelated CEPH LCLs (for the replication set) were used to generate carboplatin sensitivity variables (IC_{50} values) at concentrations of 0, 10, 40, and 80 uM of carboplatin for 72 h. The SNP genotype and baseline gene expression data of the corresponding LCL samples were downloaded from the International HapMap database (http://www.HapMap.org) and GEO (GenBank Accession No. GSE7761), respectively. This cell-based genome-wide analysis identified 342 SNPs associated with carboplatin-induced cytotoxicity, of which 18 were further found to be associated with baseline gene expression.

One of these SNPs (rs1649942) was replicated in an independent LCL set and is located within the intron of *NRG3*. This SNP genotype exhibited associations with expression levels of 10 genes; the expression levels of 7 of those genes (*ALDH2*, *CRIM1*, *KYNU*, *LOC100131869*, *OAS1*, *RAPGEF5*, and *SLC2A5*) were negatively correlated with carboplatin IC_{50}, while those of 3 genes (*BCR*, *PSTPIP2*, and *SHFM3P1*) were positively correlated with carboplatin IC_{50}. Moreover, it was found that this SNP was associated with progression-free survival (PFS) and overall survival (OS) in phase I analysis of 377 Australian ovarian cancer patients who received at least 4 cycles of carboplatin-based chemotherapy. That is, the risk allele of rs1649942 was associated with a modestly increased risk of disease progression and death following carboplatin-based chemotherapy. However, this finding was not replicated in a larger second-phase evaluation of patient samples, possibly due to differences in clinical definitions and ethnic heterogeneity between the two clinical samples.

In an earlier study, it was shown that LCLs treated with simvastatin (a cholesterol synthesis inhibitor) induced differential expression of full-length and alternative splicing variants of the statin target gene *HMGCR* (3-Hydroxy-3-methylglutaryl coenzyme A reductase) [85]. Statin is known to reduce low-density lipoprotein cholesterol (LDL-C) by inhibiting *HMGCR*, a rate-limiting enzyme for cholesterol synthesis. Such differential induction of *HMGCR* transcripts was associated with *in vivo* response to simvastatin treatment. Greater *in vitro* induction of an alternative splicing variant in LCLs was significantly associated with smaller *in vivo* absolute and percent reductions of total cholesterol, LDL-C, apoB, and triglycerides. Interestingly, *in vivo HMGCRv_1* expression in the absence of statin was not associated with *in vivo* lipid or lipoprotein measurements at baseline.

A major limitation of this approach is that *in vitro* measurements of gene expression were assessed in statin nontarget tissue; statin's primary target tissue is liver. However, there have been many reports that gene expression of lymphocytes or LCLs may reflect nonlymphoid gene expression and may be a marker for hepatic cholesterol metabolism with concordant *HMGCR* regulation between liver and peripheral blood cells [1]. Thus, using both *in vitro* differential isoform induction and *in vivo* drug response facilitates the discovery of new drug targets for improving drug efficacy, and provides a bridge between LCL findings and clinical transitions.

6.4.3 Immunological Studies Using LCLs

6.4.3.1 A Source of Neutralizing Antibodies for Serotherapy

EBV-transformed B cells preserve the immunological characteristics of the original B cells with regard to EBV receptors, complement receptors, surface immunoglobulin, and secretory immunoglobulin [86]. Before EBV transformation, memory B cells carrying appropriate surface immunoglobulin receptors can be preselected by several methods (e.g., fluorochrome-tagged antigens, subcloning, resetting with antigen-coupled erythrocytes). Alternatively, LCL clones producing specific antibodies of interest can be selected from EBV-transformed B cells after EBV infection. These LCLs will carry the appropriate surface immunoglobulin and also secrete the corresponding antibody [87,88]. However, difficulties in cloning LCLs impeded their utilization as a source of antibody-producing cells for immunotherapy.

Traggiai et al. [89] reported an improved method for EBV immortalization of human memory B cells that fully exploits the potential of the human immune response. They found that the TLR9 agonist CpG increased the efficiency of EBV B-cell immortalization by more than 100-fold and facilitated LCL cloning. The LCL clones were stable and secreted antibodies at a high rate (10–50 mg/L in the culture supernatants), which is applicable to antibody production for preclinical studies.

6.4.3.2 A Source of Antigen-Presenting Cells for Immunotherapy

In addition to a source of antibody-producing cells, LCLs that express particular antigens are useful sources of the autologous antigen–presenting cells (APCs) that are often required for restimulating human antigen-specific cytotoxic T lymphocytes (CTLs). Based on the fact that LCLs are potent antigen-presenting cells, their utility was investigated for cancer vaccines against hematological neoplasias and solid tumors [90] and pancreatic cancer [10]. For example, cancer testis antigen- (CTA-) specific T cell response was considerably induced by DNA methyltransferase 1 inhibitor alone or in combination with histone deacetylase inhibitors, which increased CTA genes in LCLs. The autologous SP-LCL was shown to be a good source of antigen-presenting cells (APCs) for cancer immunotherapy against EBV-associated malignancies, including Burkitt's lymphoma, Hodgkin's disease, and nasopharyngeal and gastric carcinomas [91,92].

6.4.4 Stem Cell Research Using LCLs

6.4.4.1 A Source Material of Induced Pluripotent Stem Cells

Recent reports shed light on potential applications of LCLs in generating human-induced pluripotent stem cells (iPSCs) from patient- or healthy donor–derived LCLs via the virus-free episomal method [93,94]. Generally, viral vectors have been used to generate iPSCs where vectors and transgenes are integrated into the genome. This integration problem hampers practical use of iPSCs for clinical applications. Generating LCL-derived iPSCs facilitates the development of human disease models and novel drug therapies. Recently, Choi et al. [93] demonstrated that patient-derived LCLs can be reprogrammed into iPSCs via a virus-free and integration-free method.

Briefly, alpha1-antitrypsin–(AAT-) deficient patient-derived EBV-transformed B cell lines were transfected by EBNA-1/OriP-based episomal vectors encoding a combination of reprogramming genes, including *c-Myc*, *KLF4*, *NANOG*, *LIN28*, and SV40-T antigen. LCL-derived iPSCs exhibited the characteristics of pluripotent stem cells; expressed pluripotency markers, including *TRA-1-60*, *SSEA4*, *OCT4*, and *NANOG*; retained inherited disease-specific donor mutation; and maintained the parental rearranged IgG/V(D)J locus. These patient-specific LCL-iPSCs could differentiate into all three germ layer cell types (endoderm, mesoderm, and ectoderm) as well as directly into mature hepatocyte-like cells (DE cells → hepatic progenitor cells → hepatocytes). These cells also showed no integration of the episomal reprogramming-related transgenes or EBV-related genes, and recapitulated an important disease feature after directed differentiation.

Rajesh et al. [94] also demonstrated that LCLs are reprogrammable to iPSCs via a virus-free and integration-free method using OriP/EBNA-1 plasmid vectors encoding reprogramming genes under feeder-free conditions. They found that a minimal combination of *OCT3/4*, *SOX2*, *NANOG*, and SV40-T antigens was sufficient for reprogramming LCLs, and that iPSCs lost EBNA-1 gene expression as well as the other EBV viral activities after subculture (more than p10 passages) due to the gradual loss of episomal vectors in the absence of drug selection. These LCL-derived iPSCs can be differentiated *in vitro* into hematopoietic, cardiac, neural, and hepatocyte-like lineages.

Thus, LCL-derived iPSCs might provide a useful tool in studying human disease modeling and drug target screening in target-specific cells of interest. LCL-derived iPSCs can take advantage of the easy manipulation of and large quantity of LCL cells. For example, as large collections of LCLs have been generated in population-based or disease-based biobanks in last the decades, LCL cells from patients with rare diseases or from the family pedigree can be easily accessible in many biobanks. More important, many LCL collections have been provided to individual studies or to international genomics or genetics consortia in order to release information about genetic variants and gene expression profiles that can be linked to donor health information, including epidemiological and clinical data. For these reasons, patient-derived

LCL-iPSCs are valuable for disease modeling, especially for rare diseases [95].

6.4.5 Factors to Consider in LCL Applications

6.4.5.1 Nongenetic Confounding Factors

Many LCL application studies showed that interindividual variations in drug-induced LCL growth inhibition are independent of basal growth rate and cell density of each cell line. For example, Morag et al. [82] reported observing no correlations between the degree of paroxetine-induced cell growth inhibition either with cell numbers (basal cell growth rate) 24 h prior to drug exposure or with cell densities immediately prior to drug exposure. This study presented a novel *in vitro* method for distinguishing shared versus distinct drug pathways, demonstrating that drugs with shared pathways exhibit a similar degree of cell growth inhibition while drugs with distinct pathways exhibit different cell growth inhibition profiles. Thus a useful tool is provided for *in vitro* assessment of *in silico*–generated drug pathway predictions and for distinguishing shared versus distinct pathways for compounds of interest.

In addition Fry et al. [83], reported massive differences in sensitivity across a panel of LCLs exposed to a DNA-alkylating agent, N-methyl-N′-nitro-N-nitrosoguanidine (MNNG). LCLs' MNNG sensitivities were not associated with individual differences in growth characteristics (e.g., cell doubling time), so it is likely that interindividual variations in drug response may be attributed to inherent LCL genetic diversity. However, there are many nongenetic confounding factors, as well as biological noise, that may affect *in vitro* assay results for interindividual differences in drug response.

Indeed, one recent study reported biological noises and *in vitro* artifacts that may reduce the ability to detect true relationships and create the potential for nongenetic confounding, causing spurious associations between genetic variants and traits (e.g., expression phenotypes, drug sensitivity) Choy et al. [96] found that the degree of drug response of individual LCLs was similar among three anti-cancer drugs (e.g., 5-fluorouracil, 6-mercaptopurine, and methotrexate), and that the baseline growth rate of individual LCLs was highly correlated to the relative responses to these drugs. Such a correlation could imply the possible influence of an experimental confounder, but it could also suggest a shared genetic mechanism common to these anti-cancer drugs. In fact Morag et al. [82], reported that paired drugs sharing a similar pathway exhibited similar growth inhibition profiles in LCLs, but not drugs with different pathways. For example, good correlations were observed in LCLs for drug responses among antidepressants (e.g., paroxetine, imipramine, fluvoxamine, amitriptyline), among antipsychotics (e.g., clozapine, haloperidol), and among steroid drugs (e.g., dexamethasone, prednisolone, beclomethasone). In contrast, no correlation was found for drug responses in LCLs between antidepressants (e.g., paroxetine) and anticancer drugs (e.g., 6-mercaptopurine, resveratrol, 5-fluorouracil, methotrexate) or between anticancer drugs (e.g., 5-fluorouracil, methotrexate, 6-mercaptopurine).

In utilizing LCLs in pharmacogenomic studies, one should pay careful attention to the many nongenetic confounding factors that may be introduced somewhere in the processes of LCL generation and maintenance as well as in the measurements of cellular phenotypes (Figure 6.3). Biological noises and *in vitro* artifacts are possibly due to the random choice of B-cell subpopulations for EBV-mediated transformation and subsequent clonal expansion of EBV-infected B cells, cell passage numbers, batch effects (including day-to-day variations in all trait measurements and cell culture conditions), and different EBV viral loads per cell, as well as baseline growth rate, ATP levels, and the measurements used to assess drug responses and mRNA expression phenotypes. Therefore, in order to rule out any influence of these potential confounders, additional validation of the assay should be conducted to establish the intra- and interday reproducibility of cellular phenotype measurements.

6.4.5.2 Replication and Functional Validation

Besides the nongenetic confounding factors discussed in the previous section, EBV transformation may affect interindividual variations in cellular phenotypes, including mRNA expression profiles and LCL drug sensitivities of LCLs. EBV-infected B cells undergo a certain degree of biological and genomic changes compared to primary B cells, and they become established immortal cell lines during long-term subculture. EBV transformation effects may vary not only in batch-to-batch LCL generation from the same donor but also in diverse cell lines from different donors. Such EBV transformation may often cause the LCL chromosomal instability and cellular changes that contribute to the possibility of false-positive results in further association studies. EBV transformation effects as well as many potential *in vitro* confounders (batch effects, baseline growth rate, cell passage numbers, etc.) can be compromised by functional validation experiments of such initial findings from LCLs. Thus studies using LCLs need to be functionally validated in other assay systems such as siRNA knockdown experiments in LCLs, or in different cancer cell lines such as the NCI-60 tumor cell line panel. They also need to be further replicated in relevant tissues and in clinical populations.

FIGURE 6.3 **Genetic and nongenetic confounding factors that affect LCL *in vitro* assays.** *Source: Adapted from Choy et al.* [96].

The LCL-based cell model has many advantages over clinical settings, and LCLs are an unlimited source of cellular and genomic materials. For example, LCLs can be easily generated from small amounts of peripheral blood and grown in well-controlled culture conditions, which allows genetic components to be tested without *in vivo* confounders, including comorbidities, dosage, timing, and diet, as well as population stratification or admixture. Moreover, LCLs allow phenotypic measurements (e.g., sensitivities to radiation or chemotherapy) that would be considered unsafe in healthy volunteers or patients. Table 6.2 summarizes some of the advantages and limitations of pharmacogenomic studies in clinical settings and cell-based models [97].

However, the LCL-based assay model has limitations in pharmacogenomic studies. A major limitation is that LCLs represent only one specific lymphoid tissue type. Although some reports have shown that LCLs can be used to discover genetic components or target genes of nonlymphoid neurological diseases such as schizophrenia and autism, LCLs' single lymphoid tissue specificity has hampered their use in pharmacokinetic studies that should be carried out on the human body or in different cell types and organs. This limitation may be overcome in certain cases if LCLs are reprogrammed to various cell and tissue types by iPSC technology.

Other limitations include EBV transformation effects and nongenetic confounding factors, as discussed in the previous section. Such biological noise and *in vitro* artifacts may affect phenotype measurements and subsequent analyses. Taking these limitations into account, initial pharmacogenomic findings using LCLs should be replicated in relevant tissues with functional validation studies, and tested for recapitulation in clinical populations.

6.5 FUTURE PERSPECTIVES

Modern health sciences need an unprecedented number of samples and their associated health data from general populations or disease patients. Well-organized biobanks and information derived from omics and health data have become necessary for the discovery and validation of biomarkers. In the era of big data, personal genetic data, health information, and environmental exposure data will be vigorously combined to accelerate the realization of predictive, personalized, preventive, and participatory medicine [98]. Moreover, statistical power will be crucial in genetic studies of common complex diseases as well as rare diseases and rare drug responses. Thus, harmonization and data sharing will be necessary to achieve the statistical power sufficient for biobank research, including population genetics and pharmacogenomics.

Until now, most cases of LCL applications in pharmacogenomic studies have utilized growth inhibition profiles of drug-treated LCLs to assess cytotoxicity of drugs of interest or environmental stresses such as radiation. Although

TABLE 6.2 Advantages and Limitations of Human and Cell Models

In Vivo Clinical Samples	*In Vitro* Cell Models
Advantages	
• Most relevant study system • Pharmacokinetics as well as pharmacodynamic testing possible • Ability to analyze effects of interactions of multiple tissues • Allows investigation of environmental factors and drug-drug interactions	• Ease of experimental manipulation • Controlled testing system free of *in vivo* confounders • Ability to test drugs with narrow therapeutic index • Genetic and expression data publicly available for hundreds of established cell lines • Cost-effective • Unlimited resources of cellular and genomic materials • Can be used for functional validation of genetic variants
Limitations	
• Difficult to collect large cohorts of patients for discovery and replication • Can be difficult to parse effects of environment from genetic effects • Ethical issues with studying drugs with narrow therapeutic indices • Not all cohorts have detailed pharmacological data, especially retrospective cohorts • Expensive and time-consuming • Require large numbers of patients and infrastructure to obtain reliable clinical phenotype data • Uncontrolled confounders (comorbidities, dosage, timing, diet, population stratification)	• Phenotype may not recapitulate *in vivo* system • Subject to *in vitro* confounders that may affect phenotypes • Cell lines can be generated only from a limited number of tissues • Cell may not express important metabolic enzymes relevant to pharmacology (e.g., cytochrome P450 family) • Establishing cell lines from tumor may alter tumor characteristics

Source: Adapted from [97].

the cytotoxicity assay is technically easy to use in studies of interindividual drug response variation in LCLs, cellular responses to drugs or environmental stresses in LCLs can be assessed by measuring other cellular phenotypes, such as intracellular ATP, Ca2+ levels or Ca2+ efflux, intracellular oxygen levels, or immunophenotypes. Developing such *in vitro* assay models for various cellular phenotypes will expand LCL applications to pharmacogenomics as well as epidemiological genomics.

The exploitation of LCLs' antigen-presenting capacity may provide *in vitro* human therapeutic antibodies against autoimmune and inflammatory diseases, as well as cancer, if the LCLs are generated using resting B lymphocytes from cancer patients. The CD40-CD154 culture system has been used to activate human B lymphocytes, resulting in the generation and clonal expansion of human B-cell lines [99]. Generally, therapeutic intravenous immunoglobulins (IVIgs) prepared from blood donors have been used to re-establish the immune system's homeostasis [99,100]. Moreover, autologous LCLs can be genetically modified to express antigens or mutated genes by transfection methods, including the virus-free episomal method.

Autologous LCLs are a good source of antigen-presenting cells for immunotherapy against cancers and immunological diseases. For example, genetically modified autologous LCLs expressing mutated Ras (muRas) successfully induced muRas-specific cytotoxic T cells in patients with muRas-related pancreatic carcinoma. On the other hand, it is possible that LCLs are generated from patients recovered from a specific disease and then clonally selected for specific autoantigens, providing a new approach to serotherapy using autologous LCLs. Indeed, the use of LCLs as a source of serotherapy has been successfully applied to isolate broadly neutralizing antibodies against SARS and H5N1 viruses [101]. These antibody-producing LCL clones open up novel applications in the field of infectious disease as well as chronic inflammatory and autoimmune disease and cancer.

LCL-derived iPSCs will provide *in vitro* tissue models to aid discovery of molecular targets of drugs and environmental stimuli that may function specifically in different target tissue or cell types (Figure 6.4). Moreover, patient LCL-derived iPSCs not only will facilitate the screening of novel drugs that can be assayed for drug effects on patient-based cell models reflecting ethnic diversity; they may also facilitate development of *in vitro* assay models to investigate cell type–specific adverse drug effects in populations. It is possible that LCL-derived iPSCs will solve the problem of representing LCLs' single lymphoid tissue specificity, which has thus far limited wide use of LCLs. They will extend the utility and application of LCLs to nonlymphoid tissues for different diseases, including brain tissue for neurodegenerative diseases, liver tissue and pancreas tissue for diabetes, and skin tissue, and they may revolutionize pharmacogenomic assay tools for personalized medicine.

Pathogens generally represent tissue specificity or cell tropism for productive life cycles. Although LCLs are derived from lymphocytes, a recent study showed the possibility that they can be used as a system for discovery of pathogen susceptibility biomarkers. If biological activities or infectivity of microbial pathogens can be fully or partially monitored in LCLs, infectious disease susceptibility may be easily investigated using them [57]. It is thus important to

develop an appropriate *in vitro* cell-based assay system to monitor host–pathogen interaction for particular pathogens in LCLs.

In general, it is easy to establish high-throughput assay systems using a single cell line. For example, a single cell type is first genetically modified to generate the reporter cell line and then grown in microtiter plates for high-throughput screening of multiple drugs. In contrast, with LCLs it is difficult to establish microtiter plates or cell arrays for high-throughput assays because multiple LCL strains are not easy to manipulate in culture at the same time. A novel LCL-based cell array therefore needs to be developed to promote high-throughput manipulation of LCLs to facilitate extended LCL application.

In the personalized medicine era, LCL utility will be extended to various fields, including a cell-based model system in discovery science and therapeutic tools in clinical settings. An international and regional consortium for LCL research may accelerate studies and applications using LCLs as well as LCL harmonization and data sharing.

ACKNOWLEDGMENTS

I would like to thank Dr. David Gurwitz at NLGIP for recommending me to write this book chapter and for his helpful advice to my LCL research. I am also grateful to Dr. Bok-Ghee Han and Dr. Sang-Ick Park for their support of the LCL research in KNIH. This work was supported by intramural grants (2013-NG74001-00, 2012-NG62002-00) from the Korea National Institute of Health and the Korea Centers for Disease Control and Prevention.

7.1 OVERVIEW

Pharmacogenomics is the study of heritable genetic variation in drug response, and aims to elucidate how genetic variants influence drug efficacy and/or toxicity. Human germline genetic variation is well known to affect drug disposition and clinical response to pharmacotherapy via genes related to both therapeutic targets and absorption, distribution, metabolism, and excretion (ADME) [1]. The Pharmacogenomics Knowledgebase (PharmGKB; www.pharmgkb.org) curates pharmacogenetic findings from the literature and, as of September 2013, lists 453 associations between germline genetic variants and drug-related phenotypes. Only 13% of these associations can be explained by genetic variation due to protein alterations as a result of changes in the amino acid sequence. However, genetic variation can impact ADME gene expression and clinical outcomes on numerous levels, including gene transcription, alternative splicing (AS), transcript stability, and rate of translation, as well as protein expression, function, and degradation [2,3]. As a result, mRNA transcript levels provide clearly defined and measurable traits that may act as intermediates for drug-related phenotypes.

Genetic variants that associate with gene expression are known as expression quantitative trait loci (eQTL) and can be further characterized as *cis* or *trans*. *cis*-eQTL are located near the expressed gene, usually within 1 Mb, while *trans*-eQTL are located further away, sometimes on a different

Handbook of Pharmacogenomics and Stratified Medicine. http://dx.doi.org/10.1016/B978-0-12-386882-4.00007-4

chromosome than the expressed gene. eQTL can refer to any type of genetic variation, but most often indicate that a single-nucleotide polymorphism (SNP) is associated with the transcript level of a gene. The interrogation of SNP genotypes and transcript levels has generally been performed using oligonucleotide microarray platforms, enabling the identification of eQTL through genome-wide analyses [4]. This linking of gene variation and expression may clarify the pharmacogenetic significance of genes of interest [5] and thus eQTL have significant potential utility for the study of pharmacogenomics.

Lymphoblastoid cell lines (LCLs) have been the predominant model for eQTL analyses in humans [6]. These cell lines are derived from B-lymphocytes transformed by the Epstein-Barr virus (EBV). Although this transformation provides an immortalized cell line that can be directly examined in pharmacogenomic studies [7–9], nongenetic factors—including the life history of the human donor, the B-lymphocyte subtype selected, the EBV titers used for transformation, the culture conditions under which the cells are grown, and the intrinsic characteristics of lymphoblastoid cells—can affect gene expression and limit the utility of LCLs for these studies [10]. Nevertheless, several studies have incorporated LCL eQTL findings in clinical pharmacogenomic studies (reviewed in Wheeler et al. [11]).

In the context of clinical pharmacogenomics, the liver may be the most relevant tissue in which to perform eQTL analyses. It is the predominant organ in drug elimination, with 75% of the 200 most widely prescribed drugs being eliminated from the body through liver metabolism or biliary excretion [12]. Furthermore, a significant number of ADME genes are strongly expressed in the liver. Schroder et al. [13] defined a list of 682 ADME genes from various pharmacogenomic resources. The expression of 61 of these genes has been predicted to be liver-specific according to a study of gene expression in human tissues [14], indicating that eQTL of these genes may not be detected in other tissues. In addition, eQTL may have effects at the molecular level that depend on the cell or organ in question. Therefore, knowledge of liver eQTL could provide a foundation for clinical pharmacogenomic research.

7.2 LIVER eQTL STUDIES

We are presently in the early stages of liver eQTL research, and only five genome-wide eQTL studies have been reported that describe the analysis of primary human liver tissue (Table 7.1). However, these studies have led to the identification of several thousand eQTL, after correction for multiple testing, and many of the eQTL single-nucleotide polymorphisms (eSNPs) associate with the expression of ADME genes.

7.2.1 Liver eQTL in Pharmacogenetic and Clinical Genome-Wide Association Studies

ADME genes with liver eQTL, which pass multiple correction thresholds in one of the five genome-wide association studies (GWAS), include *COMT*, *CYP2D6*, *CYP2E1*, *CYP3A4*, *CYP3A5*, *GSST1*, *MTHFR*, *UGT1A1*, and *VKORC1* (Table 7.2). These genes belong to a set of 50 "very important pharmacogenes" (VIPs) that are known to effect drug response phenotypes and have been identified by the PharmGKB resource (http://www.pharmgkb.org/search/browseVip.action?browseKey=vipGenes) as having particular relevance to pharmacogenetics and pharmacogenomics. In addition, several of the eSNPs identified in these studies are markers of pharmacogenetic associations (Table 7.2). These findings demonstrate that liver eQTL may help explain the association of SNPs with clinical phenotypes and provide a rationale for using liver eQTL data from relevant genes to select candidate SNPs for pharmacogenomic study. For example, Schadt et al., [15] identified an eSNP in *COMT* (Table 7.2). This gene encodes catechol O-methyltransferase (COMT), an enzyme that metabolizes catecholamine neurotransmitters, including dopamine, epinephrine, and norepinephrine; also, a *COMT* SNP has been associated with antidepressant drug response [16]. COMT protein is known to exist in two forms, resulting from the use of alternative promoters, and the enzymatic activity of these two isoforms has been demonstrated to vary as a result of altered protein expression.

The role of *COMT* in treatment-resistant major depressive disorder is thought to be related to decreased norepinephrine and dopamine availability resulting from expression of the high-activity enzyme. Therefore, determining the effect of this liver eQTL on mRNA transcript levels, as an intermediary to protein isoform expression, may offer an explanation for these differences in metabolism and thus a basis for the association of this gene with psychiatric phenotypes. Cytochrome P450 (CYP, P450) 2D6 is another important drug-metabolizing enzyme, with the PharmGKB estimating that it is involved in the metabolism of up to 25% of commonly prescribed therapeutics [17]. Additionally, CYP2D6 is the only noninducible drug-metabolizing CYP; therefore, genetic variation contributes significantly to interindividual variability in the activity of this enzyme. Three eSNPs have been identified in the *CYP2D6* gene as a result of liver eQTL studies (Table 7.2) and each could conceivably be used to test associations with pertinent clinical phenotypes of any of the 46 drugs that, according to PharmGKB-curated information (http://www.pharmgkb.org/gene/PA128#tabview=tab6&subtab=21), are metabolized by the CYP2D6 enzyme.

In contrast to CYP2D6, CYP2E1 makes up a much smaller proportion (<1%) of total hepatic P450 and plays a more minor role in the metabolism of clinical drugs. The anti-tuberculosis drug isoniazid, however, has been shown to be both a substrate for and an inducer of CYP2E1 protein, although it does not increase mRNA levels. Based on these findings, it is thought that protein expression levels may be regulated by increased translational efficiency

TABLE 7.1 Summary of Human Liver eQTL Studies

Category	Schadt et al.	Innocenti et al.	Schroder et al.	Greenawalt et al.	Fu et al.
Samples in final analysis	384	206	149	651	74
Race	All Caucasian	183 European American; 23 African American	All Caucasian	86% of overall cohort Caucasian	All Caucasian
Nature of liver tissue	Postmortem tissue and resections from donor livers	Postmortem tissue and resections from donor livers	Normal tissue resected during surgery for liver cancer	Tissue from morbidly obese patients undergoing gastric bypass	Liver wedge biopsies from morbidly obese patients undergoing gastric bypass
Covariates	Age, sex, medical center	Age, sex, genetic ancestry, effects of array hybridization and oligonucleotide probes, surrogate variables	Age, sex, smoking, alcohol consumption, diagnosis, C-reactive protein, cholestatic liver disease, presurgical medication	Age, sex, medical center	Removed first 50 PCs

and/or protein stabilization. eSNPs have been demonstrated to exert regulatory effects on gene expression post-transcriptionally via mechanisms such as AS and altered 3′-untranslated regions (UTRs). Therefore, a mechanistic role to explain the increased risk of isoniazid-induced liver toxicity associated with *CYP2E1* variants having increased enzyme activity and inducibility could be investigated for the liver eQTL identified by Schadt et al. At the opposite end of the spectrum of human hepatic P450s from *CYP2E1* is the *CYP3A* family, including *CYP3A4* and *CYP3A5*. The proteins encoded by these genes together account for approximately 30% of total human hepatic CYPs and are responsible for the metabolism of >50% of all currently prescribed pharmaceuticals. PharmGKB has curated information for 72 drugs. (http://www.pharmgkb.org/gene/PA130?tabType=tabVip#tabview=tab6&subtab=21) and 67 (http://www.pharmgkb.org/gene/PA131?tabType=tabVip#tabview=tab6&subtab=21) drugs that are substrates for CYP3A4 and CYP3A5, respectively, although significant overlap in specificity exists. Numerous pharmacogenetic associations between *CYP3A4/5* SNPs and drug efficacy or toxicity phenotypes have been identified and, as was described for *CYP2D6*, the *CYP3A4* and 2 *CYP3A5* eSNPs identified from liver eQTL studies could be tested for association with relevant clinical outcomes with any of the known drug substrates.

Phase II enzymes also play a prominent role in pharmacogenetic phenotypes by facilitating detoxification through conjugation reactions that increase solubility and thus aid the elimination of conjugated compounds from the body. Glutathione S-transferase (GST) theta (GSTT1) and uridine diphosphate glucuronosyltransferase (UGT) 1A1 catalyze the conjugation of a number of chemotherapeutics with glutathione and glucuronic acid, respectively, and expression level variation in these genes represents significant potential for altered efficacy and/or toxicity of cancer therapies.

[2] *LD determined from 1000 Genomes Pilot 1 CEU data using SNAP browser (http://www.broadinstitute.org/mpg/snap/ldsearch.php).*

Note: PharmGKB currently identifies 50 genes of particular importance in pharmacogenomics (http://www.pharmgkb.org/search/browseVip.action?browseKey=vipGenes).

Although more than 130 variants in *GSTT1* are cataloged in the National Center for Biotechnology Information (NCBI) Single Nucleotide Polymorphism Database (dbSNP) [18] as of September 2013, the relevance of most of these SNPs is unknown, as functional roles for only a few have been established through studies reported in the literature and only one pharmacogenetic association has been identified to date. However, a number of associations have been identified between the *GSTT1* null variants (i.e., the partial or complete deletion of the *GSTT1* gene) and adverse drug reactions [17]. Gamazon et al. [19] have shown that SNPs that are in strong linkage disequilibrium (LD) ($r^2 = 0.8$) with copy number variants (CNVs) are more likely to be LCL eQTL. This highlights an area for further investigation of the liver *GSTT1* eSNPs identified by Schadt et al. [15] and Schroder et al. [13].

As opposed to the paucity of data in the literature on genetic variants and pharmacogenetic associations in *GSTT1*, there are 113 known genetic variants in *UGT1A1*, with a number of these known to associate with the development of drug toxicities [17]. In Schroder et al.'s study [13], rs2070959 was identified as a *UGT1A1* eSNP. This variant has not been well studied, and the role it plays in altered UGT1A1 enzymatic phenotypes and possibly the prediction of drug toxicities is yet to be explored. Finally, five liver eQTL were identified in *VKORC1,* a gene with polymorphisms known to account for approximately 25% of interindividual variability in warfarin dose. Two of these eSNPs were in perfect LD ($r^2 = 1$) with PharmGKB pharmacogenetic SNPs, while the remaining three have not been identified as markers of known pharmacogenetic associations. SNPs in *VKORC1* are associated with both high and low warfarin dose phenotypes, and liver eQTL may aid in explaining the role of gene regulation in this variability.

In addition to helping explain the association of SNPs with clinical phenotypes, liver eQTL data can be used to inform GWAS. GWAS have identified many SNPs associated with clinical traits in humans. Typically, there is no mechanistic explanation for the association, but eQTL could help fill this knowledge gap. In the liver eQTL studies conducted to date (Table 7.1), Greenawalt et al. [20] and Schadt et al. [15] identified 121 and 21 eSNPs, respectively, which were significantly associated, after multiple test correction, with a clinical phenotype in a GWAS. Innocenti et al. [21] identified 32 eSNPs that are significant GWAS SNPs or markers for a GWAS SNP through strong LD ($r^2 > 0.8$). In fact, there is a significant enrichment of eSNPs among SNPs associated with clinical phenotypes in GWAS [22]. However, a critical piece of information lacking from these reports is the directionality of the eQTL association (i.e., which allele associates with higher/lower transcript levels), and thus hypotheses about the effect of a specific allele cannot be generated.

For GWAS SNPs that are associated with a clinical phenotype and located in intergenic regions, there is often ambiguity about which gene the SNP is regulating. eQTL data can also be used to aid this determination. Identifying gene expression levels associated with a GWAS SNP provides evidence to suggest that a gene may be a susceptibility or protective factor for the clinical phenotype. Schadt et al. [15] provide examples of intergenic eSNPs that were found to associate with type 1 diabetes, coronary artery disease, and LDL cholesterol levels in GWAS.

7.2.2 Liver eQTL Reproducibility

There are many factors related to liver eQTL studies that could act as confounders and affect eQTL reproducibility. First, these studies used a variety of tissue sources from individuals with different ethnic backgrounds (Table 7.1), including resections of normal tissue from patients suffering from liver cancer [13], morbid obesity [20], or otherwise healthy, deceased liver donors who may have undergone multiple pharmacotherapeutic treatments immediately prior to death [15,21]. Second, different genotyping and gene expression platforms and analysis methods were used to identify eQTL (Table 7.1). Furthermore, the studies controlled for different covariates and had variable power due to the number of samples, genotypes, and transcripts interrogated (Table 7.1).

Despite these issues, there is evidence that a substantial proportion of the *cis*-eQTL findings are reproducible. Innocenti et al. [21] attempted to replicate findings from their eQTL study in two additional datasets, one of which was a subset of samples from the Schadt et al. study. Sixty-seven percent of the significant *cis*-eQTLs (Bayes factor $(BF) > 5$) replicated in at least one of the additional datasets ($p < 0.05$ and concordant effect direction), but this replication rate dropped to 6% for *trans*-eQTLs ($BF > 5$) [21]. Greenawalt et al. [20] also examined the reproducibility of their liver *cis*-eQTL ($FDR < 10\%$) in the Schadt et al. study, which used the same microarray gene expression platform and found a 66% overlap. Using Bonferroni adjusted p-values, a much more stringent analysis—a comparison between the Schadt et al. and Schroder et al. studies—showed that only 16% of the *cis*-eQTL replicated and there was no replication of *trans*-eQTL [13]. Neither of the latter two studies state whether a concordant effect direction was a criterion for replication, but it appears that liver *cis*-eQTL are comparatively reproducible while *trans*-eQTL are not. This observation may be partly explained by statistical power. Compared with *cis*-eQTL, *trans*-eQTL have a greater multiple test correction burden and thus are less likely to achieve statistical significance in two independent studies.

A salient finding in the Innocenti et al. study [21] was that the *cis*-eSNP with the highest BF in each gene was frequently located immediately upstream or downstream of the transcription start site (TSS) of the eQTL target gene. Additionally, 75% of *cis*-eQTL within 100 kb of the TSS were found to replicate, compared to 61% of those located more than 100 kb from the TSS [21]. Furthermore, Schadt et al. [15] noted that 70% of the *cis*-eQTL were found within 100 kb of the TSS. Therefore, it appears that reproducible liver *cis*-eQTL SNPs are generally found close to gene TSSs. This suggests that eSNPs may directly impact gene transcription by altering gene regulatory regions.

7.2.3 Liver eQTL Tissue Specificity

To examine liver eQTL tissue specificity, Schadt et al. compared their findings with eQTL analyses of human blood and adipose tissue [23]. Approximately 30% of the *cis*-eQTL identified in these tissues were also detected among the liver eQTL (FDR < 10%) from their study [15]. Kabakchiev and Silverberg [24] compared eQTL identified in human ileum, another tissue known to highly express ADME genes, with the liver eQTL identified in the Schadt et al. study [15]; they found that approximately 37% (FDR < 5%) and 43% (FDR < 10%) of significant hepatic *cis*-eQTL were replicated in the intestine. Greenawalt et al. [20] examined replication of their liver *cis*-eQTL in adipose tissue from the same cohort of individuals used for liver eQTL analysis, finding that 46–48% of the liver *cis*-eQTL replicated at $p < 0.05$. Moreover, they found that liver eQTL, but not eQTL identified from adipose tissue, were enriched for the KEGG pathway *drug metabolism–cytochrome P450 genes*. Furthermore, of the 11 ADME genes that had reproducible eQTL between the Schroder et al. and Schadt et al. studies [13,15], *CYP3A5*, *DHRS2*, and *SLC22A3* have been predicted to be preferentially expressed in the liver based on analysis of tissue-specific expression profiles [25]. These findings suggest that at least some fraction of the genetic control of gene expression is specific to the liver.

On the basis of comparisons of eSNPs and gene expression in the liver, subcutaneous and visceral adipose tissue, blood, and skeletal muscle, Fu et al. [26] identified four categories of tissue-dependent *cis*-regulation of gene expression: specific regulation, alternative regulation, different effect size, and opposite allelic direction. It has been demonstrated that rs12740374, which maps to the *SORT1* gene, alters the binding site for C/EBP transcription factors (TFs), consequently modulating hepatic expression of *SORT1* and affecting low-density lipoprotein cholesterol and myocardial infarction risk [27,28]. This eQTL replicated in liver samples but not in blood, subcutaneous and visceral adipose, or skeletal muscle, despite abundant expression of *SORT1* in all tissues, which indicates liver-specific regulation of *SORT1* via this eSNP [26]. In a hepatic example of alternative regulation, rs714885 was found to associate with the regulation of *TMEM176A* (hepatocellular carcinoma-associated antigen 112) expression in the liver; however, an independent, unlinked (LD $r^2 = 0.002$) variant, rs6464104, was found to regulate expression levels of this gene in blood [26]. Even in instances where eQTL and gene associations have not been found to be tissue-specific, variance in both the magnitude and the directionality of effect across tissues has been noted. Specifically, the same eSNP associated with expression levels of D-dopachrome tautomerase (*DDT*) in both blood and liver; however, its effect on expression levels exhibited completely opposite directionality in these tissues. Such findings underscore the complexity of unraveling causative genetic variants as well as the mechanisms by which they mediate tissue-dependent expression, and they reiterate the importance of investigating phenotypicallly relevant tissues.

7.2.4 Correlation of Liver eQTLs and CYP Enzyme Activity

Gene transcript levels are a useful intermediate phenotype to study, but measurements of protein levels or enzyme activity may provide a more informative phenotype for pharmacogenomics. One of the advantages of the liver eQTL model is that subcellular fractions can be generated from the liver, allowing proteomic and biochemical studies to be integrated with genomic and transcriptomic data from the same tissue. For example, Yang et al. [29] examined the enzymatic activities of eight CYP proteins using liver microsomal samples derived from the same cohort used by Schadt et al., [15] and found that the activities of the CYPs were positively correlated with mRNA transcript levels after adjusting transcript and activity levels for age, sex, and study site. Transcript levels explained 10–30% of the variance in enzyme activity, indicating that other biological and maybe environmental or unexplained factors, such as post-translational mechanisms, may also impact activity levels. Fifty-four enzyme activity QTL (aQTL) were identified for the 8 CYP proteins: 24 SNPs were *trans*-aQTL and 30 were *cis*-aQTL (FDR < 10%) [29]. The *cis*-aQTL SNPs were all associated with CYP2D6 enzyme activity, and 29 of these were found to also be *cis*-eSNPs of *CYP2D6* (FDR < 10%). The directionality of the eQTL associations were not reported, however, so the concordance of these associations with enzyme activity cannot be determined.

7.2.5 Web-Based Liver eQTL Data Resources

The Gene Expression Omnibus (GEO) repository contains data from all of the human liver eQTL studies (Table 7.1), although genotypes from the studies carried out by Schadt et al. and Greenawalt et al. are not available. The results of the Schadt et al. study are available through the

TABLE 7.3 Repositories of eQTL Data

Repository	Website	Description
GEO	http://www.ncbi.nlm.nih.gov/geo/	Repository of gene expression data from >2500 studies
SCAN	http://www.scandb.org	Repository of SNP and CNV eQTLs identified in LCLs
eqtl.uchicago.edu	http://eqtl.uchicago.edu/cgi-bin/gbrowse/eqtl/	Genome browser with eQTL annotations
GTEx	http://www.ncbi.nlm.nih.gov/gtex/GTEX2/gtex.cgi	Repository of eQTL data from different tissues

Genotype-Tissue Expression (GTEx) eQTL browser (http://www.ncbi.nlm.nih.gov/gtex/GTEX2/gtex.cgi) and can be queried by gene or SNP and filtered by p-value or LD r^2 values. The GTEx browser provides further useful information by annotating corresponding eSNPs with significant findings from GWAS. While the GTEx eQTL browser currently contains information regarding previous studies, the ongoing Genotype-Tissue Expression (GTEx) project [30] will provide a large-scale database and tissue bank for eQTL analysis across a wide range of human tissue types. The University of Chicago eQTL browser (http://eqtl.uchicago.edu/cgi-bin/gbrowse/eqtl/) provides a graphical display of eQTL identified from numerous studies, including those of Schadt et al. and Innocenti et al., within a user-defined genomic interval, and also provides a means for users to upload their own eQTL annotation for viewing in conjunction with the available published eQTL data. Similarly to the University of Chicago eQTL browser, the seeQTL searchable browser and database [31] employs a graphical user interface to explore eQTL data within genomic intervals; although currently only containing data from brain, monocyte, and LCL eQTL studies, seeQTL plans to incorporate liver eQTL data in the near future. Other GWAS and gene expression repositories as well as additional web-based genomics resources have been extensively reviewed by Glubb et al. [32] Web-based liver eQTL repositories are listed in Table 7.3.

7.3 FUTURE DIRECTIONS

7.3.1 Next-Generation Sequencing

Earlier liver eQTL studies interrogated genetic variation and gene expression at the genome level. Early GWAS studies, in contrast, were based on the assumption that variation in common phenotypic traits is primarily due to common variants. Therefore, SNP coverage was limited to genotyping high-density SNP chips to variants with minor allele frequencies of greater than 5%, and sample sizes for most GWAS studies were underpowered, making them unable to detect the effects of less common and rare variants, despite the fact that both common and rare variants have been identified in many genes affecting drug metabolism and transport [33]. Because of the limitations of high-density SNP chips, the variants identified by GWAS to date are able to explain only a small fraction of the clinical phenotypes examined. Since the minor allele frequencies of uncommon and rare variants are below the threshold of inclusion on commercially available genotyping SNP chips, delineating the effects of these variants on gene expression is best accomplished through sequencing.

Still relatively expensive, NGS nevertheless has advanced to the point where it is becoming feasible to perform whole-genome sequencing of DNA and mRNA to comprehensively characterize genetic variation and the entire transcriptome in a relatively large number of samples. However, sequencing costs for the number of subjects required for a rare-variant GWAS of a complex trait are still prohibitive. Genotype imputation can be performed using data from projects such as HapMap and 1000 Genomes Project to greatly increase the number of genotypes interrogated through high-density SNP chips. In this way, most of the variation accessible through sequencing is captured. Indeed, Innocenti et al. [21] imputed genotypes from HapMap to generate more than 2 million genotypes. Imputation can also be used in conjunction with low-coverage sequencing as a more economical means of genotyping less common and rare variants. However, imputation-based methods, are limited by the depth of available reference panels; variants that are too rare to be represented in a reference panel cannot be imputed.

In addition to the genotyping challenges presented by high-density SNP chips, transcriptome information obtained via microarray technologies has been limited by reliance on existing knowledge about the genome sequence, decreased sensitivity as a result of cross-hybridization of probes and targets, and reduced dynamic range of detection due to background hybridization and signal saturation, making it difficult to detect and/or quantify both high- and low-abundance species. Advances in NGS have led to the use of RNA-seq (next-generation sequencing of mRNA) to define transcriptomes. Pickrell et al. [34] found a high correlation between transcript levels quantitated by RNA-seq and microarrays. Using data from the same 53 individuals, these researchers demonstrated that 70% of SNPs previously identified as eQTL (FDR < 10%) by expression microarrays were replicated by RNA-seq ($p < 0.05$), while 93% of microarray-based associations showed concordant directionality in the RNA-seq data. Montgomery et al. [35] found that approximately 10 million sequencing reads can provide the same depth of coverage as microarrays, but because RNA-seq overcomes many of the limitations presented by microarray technology, improved resolution allows detection of more eQTL. RNA-seq has other advantages over oligonucleotide expression arrays—for example, no saturation of intensity signal for high-abundance transcripts and the ability to quantify allele-specific expression [36]. Additionally, RNA-seq can identify splicing QTL (sQTL), which may not affect overall gene expression but alter transcript isoform levels [34]; and noncoding RNAs (e.g., miRNAs, lncRNAs, etc.), which are known to play a very important role in the regulation of gene expression.

Ongoing efforts by both the Pharmacogenomics Research Network (PGRN) and GTEx are utilizing RNA-seq to create comprehensive public databases with quantitative information on gene expression and regulation in tissues of pharmacological importance. These resources will inform GWAS, provide insights into the mechanisms of gene regulation, and enable future studies of eQTL, AS, and the tissue specificity of gene regulatory mechanisms.

7.3.2 Identification of sQTL

Several thousand liver eQTL that pass multiple comparison criteria have been identified in the studies published to date; however, regulatory mechanisms remain to be elucidated for a vast majority of these associations. Using eQTL data from LCLs, Lalonde et al. [3] estimated that approximately 75% of eQTL regulate gene expression at the transcription level. The remaining 25% are thought to regulate expression levels co- or post-transcriptionally by altering mRNA splicing and/or stability. Veyrieras et al. [37] reported an enrichment of eSNPs in promoter and 3′ regions of genes, and Lalonde et al. [3] found an approximately twofold enrichment of AS events in eQTL targets. For a number of genes, Kwan et al. [38] identified splicing regulatory SNPs (sSNPs) that regulate both expression levels of LCL mRNA and the type of isoforms produced. AS within 5′ and 3′-UTRs may result in the addition or removal of regulatory sequences, thus altering mRNA translation efficiency and/or stability. The selection of an alternative splice site within the 3′-UTR may result in the differential use of stop codons or the use of alternative polyadenylation sites, both of which alter the length and composition of the 3′-UTR.

MicroRNAs (miRNAs) function as post-transcriptional regulators of gene expression by binding to the 3′-UTR of target mRNAs, which generally results in translational repression or mRNA degradation. Therefore, AS that results in altered 3′-UTR length and/or SNPs located in 3′-UTR sequences may eliminate or create miRNA targets, significantly affecting gene expression. Wei et al. [39] identified liver eQTL, or proxies in strong LD ($r^2 = 0.8$), from 12 xenobiotic metabolizing enzymes and transporters that are predicted to create, eliminate, or alter miRNA target sites, suggesting one mechanism by which eQTL might regulate gene expression.

7.3.3 Identification of miRNA eQTL

Modification of miRNA 3′-UTR target sites is only one mechanism through which the regulatory role of miRNAs is coordinated, with genetic variation in miRNA expression levels also likely to have an impact on transcript levels. Indeed, Rieger et al. [40] measured hepatic expression levels of 56 miRNAs predicted to target the 3′-UTR of ADME genes; they found numerous associations with both ADME gene expression profiles and CYP gene expression phenotypes, including mRNA and protein expression, and enzyme activity. Gamazon et al. [41] also found a significant genetic component to miRNA expression variation in the liver, identifying a set of genomic loci associated with miRNA expression levels and enriched for SNPs associated with mRNA expression. More specifically, 28 of 41 VIPs investigated were significantly (FDR < 0.05), and negatively, associated with miRNA expression in the liver. In fact, VIPs were found to be significantly enriched for large miRNA regulatory effects. Given the role of miRNAs in regulating target mRNA expression, miR-eQTL represent genetic variants with significant potential for functional pharmacokinetic and/or pharmacodynamic impact on drug response.

7.3.4 Identification of Functional eSNPs

eQTL analyses are informative, but they cannot definitively identify the causative SNPs that affect gene expression. Because of LD, many eSNPs can represent the same causative genetic variant. Various approaches can be used to identify functional genetic variants that generate the eQTL signal. Reporter gene assays are useful in determining whether eSNPs in promoter, 5′UTR, 3′UTR, and intronic regions have functional effects on gene expression [21], but they cannot be easily applied in a high-throughput fashion and the effects of SNPs in coding regions are generally not amenable to testing.

Bioinformatic analyses may help to narrow the number of putatively causative SNPs by identifying those that are located in functional genomic elements such as are defined by the Encyclopedia of DNA Elements (ENCODE) Project [42]. Among these genomic elements, DNase I hypersensitivity sites (DHS) and a variety of histone modifications have been shown to associate with regulatory regions and mark sites of active transcription and/or repression [43,44]. Indeed, studies of LCL eQTL found that 40–50% of eSNPs were located either in open chromatin regions [44], as evidenced by DNaseI hypersensitivity, or within areas of histone modification.

SNPs in DHS are four times more likely to associate with transcript levels as compared with SNPs not in active chromatin regions [44], while regions of histone modifications known to associate with active promoters and enhancers, but not regions characterized by repressive histone marks, were found to be significantly enriched in eSNPs [44]. Additional analysis of these open chromatin and histone modification regions demonstrated a significant enrichment of TF binding sites in genomic regions containing eSNPs [44], further suggesting that eSNPs have an impact on promoter and/or enhancer function. Moreover, Degner et al., [45] also using LCLs, observed a general correlation between higher DNase I sensitivity and increased TF binding site occupancy, with the genetic variant associating with increased chromatin accessibility also associating with increased gene expression levels for 70% of SNPs that modify both DHS and transcript levels. These findings suggest that epigenetic and other regulatory information can be combined with eQTL data to create a model that ranks eSNPs on their potential to affect gene expression [44]. This approach has not yet been applied to a study of liver eQTL, but could prove extremely useful in identifying pharmacogenetic variants and their target genes.

The mechanism by which distal regulatory elements, such as enhancers and TF binding sites, alter gene expression levels remains poorly understood. However, the relatively recent advent of chromosome conformation capture (3C) technology has led to an appreciation of the important role played by spatial organization of the genome in genetic regulation. The frequency of interaction between any two genomic loci can be determined using 3C and 3C-derived methodologies (e.g., circular chromosome conformation capture, chromosome conformation capture on ChIP, chromosome conformation capture carbon copy, combined chromosome conformation capture ChIP cloning, global 3C interactions, and chromatin interaction analysis by paired-end tag sequencing). These allow detailed quantitative analysis of chromosome structure [46]. Briefly, a fixative agent such as formaldehyde is used to cross-link physically touching segments of interacting chromatin throughout the genome. After proteins that are not cross-linked are solubilized, the DNA in the fixed chromatin is digested using restriction enzymes and religated under conditions that favor intramolecular ligations over ligations between random fragments. The relative frequencies with which different sites become cross-linked are then determined and are proportional to the frequency with which these genomic loci interact.

Analysis of genome-wide interaction frequencies provides information about physical properties and chromosome conformation [46]. A number of 3C studies have demonstrated the formation of chromatin loops that bring putative genomic regulatory elements into contact with target gene promoters [47]. A study by Vakoc et al. [48] directly implicated these looped interactions in gene regulation, demonstrating that disruption of the chromosomal looped conformation results in gene expression abatement. 3C approaches, in combination with other *in vitro* assays, can also inform SNP function. For example, Pomerantz et al. [49] demonstrated that a SNP associated with cancer risk is located in an enhancer sequence that interacts with the promoter of the MYC proto-oncogene and that the SNP increases enhancer activity in a luciferase assay.

Thus, 3C approaches have the ability to identify discrete genetic regions, such as enhancers or silencers, which modulate gene expression; these data can be matched with eQTL studies to determine if eSNPs are located within such regulatory regions. Furthermore, the potential allele-specific effects of eSNPs on interactions between regulatory regions and gene promoters can be examined by sequencing of the interacting region to identify the allelic variant(s) present.

7.3.5 Epistatic eQTL Interactions

eQTL analyses generally examine the effects of only a single genetic locus on gene expression. However, it is possible that interactions of *cis*- and *trans*-eQTL contribute to gene expression regulation. Indeed, in a study of HapMap LCLs, 15% of transcripts were found to be regulated by a *cis-trans* eQTL interaction while in a single-locus analysis the vast majority of the eSNPs were found not to be significantly associated with gene expression [50]. Therefore, important information may be lost by not considering these eQTL interactions, and this approach could be used to detect epistatic pharmacogenetic variants that may not otherwise be identified.

7.3.6 Copy Number Variants

While much emphasis has been placed on the interrogation of SNPs as human liver eQTL, other sources of germline genetic variation in the human genome may also function as liver eQTL. Insertion and deletions (INDELs) in the human genome, typically between 1 bp and 1 kb in length, account for a smaller fraction of genetic variation, and ongoing studies utilizing NGS approaches are building on the current catalog of almost 2,000,000 INDELs [51–55]. CNVs are classified as deletions, duplications, and insertions in the germline genome that are >1 kb in length and, although they are present at a much lower frequency than SNPs and INDELs, they may have a greater impact on phenotypic variation due to the larger fraction of the genome they encompass [53,56–58]. In the context of gene expression, the potential exists for CNVs to alter gene dosage or ablate regulatory regions in the genome; this function has been shown to explain some eQTL signals identified in LCLs [19,59].

Although the role of CNVs as eQTL has not been directly assessed in human liver tissue, pharmacogenetic studies suggest their relevance. The enzyme CYP2D6, predominantly expressed in the human liver and involved in metabolizing up to 25% of all drugs, can be found with more than two gene copies in ~5.5% of Europeans, and leads to a phenotype of increased drug metabolism [60]. One study examined the influence of CNVs in the GST family of detoxifying enzymes in a group of diffuse large B-cell lymphoma patients treated with standard chemotherapeutics. It identified copy number deletions associated with chemotherapy-related toxicities [61]. Recent studies employing genome-wide CNV analyses in LCLs identified numerous CNVs that associate with cytotoxicity for many common anti-cancer therapeutics [62,63]. These studies highlight the potential for a genome-wide assessment of CNVs as eQTL in human liver tissue as a means to enrich our understanding of pharmacogenomics. Through computational approaches to identify CNVs from SNP genotyping microarrays, the opportunity exists to utilize data from existing liver eQTL studies to gain insight into the function of CNVs as human liver eQTL [13,15,21,64].

7.3.7 Liver Protein QTL

Although gene expression levels can often serve as suitable intermediates for drug phenotypes, mRNA levels do not necessarily reflect protein expression or the functional activity of the corresponding enzyme or transporter. However, high-throughput proteome-wide quantification of protein expression has proven much more problematic and less straightforward than transcriptome quantification. Liquid chromatography–tandem mass spectrometry (LC-MS/MS) provides a way forward, but currently the best approach for sensitive and accurate protein quantitation is via targeted proteomic studies [65]. For example, targeted LC-MS/MS analysis of several UGT1A isoforms has been successfully performed in human liver microsomes [66].

Ohtsuki et al. [67] utilized a similar methodology to measure mRNA and protein expression for 12 CYP and 5 UGT enzymes as well as 12 transporters in microsomes or plasma membranes from 17 human liver biopsies. Only the mRNA expression levels of *CYP2B6*, *CYP2C8*, *CYP3A4*, *UGT1A6*, and *SLCO1B1* were highly correlated with protein expression ($r^2 > 0.6$). *CYP3A5*, *CYP3A7*, *CYP2C19*, and *CYP2D6* mRNA levels were moderately correlated ($r^2 = 0.4 - 0.6$), but the remaining enzymes and transporters investigated showed almost no correlation between gene and protein expression levels. Furthermore, only CYP2B6 enzyme activities were more highly correlated with mRNA expression than with protein expression.

Ohtsuki et al.'s study highlights the limited knowledge we have regarding differences in human hepatic protein abundance and reveals the need for protein QTL analyses to characterize the genetic regulation of protein expression. Such studies have been reported in LCL [68,69] and plasma [70,71] and demonstrate the feasibility of this approach. The integration of DNA variation, transcriptome expression, and proteome quantification will enable a more in-depth understanding of gene expression regulation and interindividual variation in pharmacokinetic and pharmacodynamic phenotypes.

7.4 CONCLUSION

There is a strong rationale for using the findings from human liver eQTL studies as a knowledge base in clinical pharmacogenomic studies. Liver eQTL analyses provide insight into the genetic regulation of ADME genes that may not be obtainable from other tissues, and they identify eQTL that are reproducible and unique to the liver. Moreover, liver eQTL data can help explain previously identified pharmacogenomic associations and provide candidates for prospective clinical study.

Pharmacogenetic studies to date have generally been able to explain only a small percentage of drug responses. In contrast, chromatin conformation signatures have the potential to significantly enhance our understanding of gene expression regulation and and our ability to identify the functional genetic variants underlying eQTL signals. Combinations of SNPs, CNVs, and other structural variants may work in concert to produce unique genomic interactions via alternative chromatin conformations that define the gene expression and pharmacogenetic variation seen in individuals [72]. Examination of liver eQTL in this context may lead to the identification of novel biomarkers of disease susceptibility and drug response. In the future, the integration of NGS, bioinformatic, epigenetic, epistatic, CNV, and protein analyses will generate a truly comprehensive map of the genetic regulation of gene expression in the liver. This is certain to profoundly impact the field of pharmacogenomics.

ACKNOWLEDGMENTS

This chapter is an update of a previously published mini-review [73]. For her contributions to the mini-review, the authors would like to acknowledge and thank Neepa Dholakia.

GLOSSARY

Alternative splicing a regulatory mechanism by which multiple mRNA transcripts are generated from a single gene

Cytochrome P450 a large superfamily of heme-thiolate proteins involved in the metabolism of a wide variety of exogenous and endogenous compounds

Copy number variants deletions, duplications, and insertions in the germline genome that are >1 kb in length

Expression quantitative trait loci genetic loci that regulate gene expression

Genome-wide association study (GWAS) analysis of DNA markers across the genome to identify variants associated with particular phenotypes

Linkage disequilibrium nonrandom association of alleles at two or more loci

Single-nucleotide polymorphism a DNA sequence variation in which a single nucleotide is altered

ACRONYMS AND ABBREVIATIONS

3C	chromosome conformation capture
ADME	absorption, distribution, metabolism, excretion
aQTL	activity quantitative trait loci
AS	alternative splicing
BF	Bayes factor
CNV	copy number variant
COMT	catechol O-methyltransferase
CYP	cytochrome P450
dbSNP	single-nucleotide polymorphism database
DHS	DNase I hypersensitivity sites
ENCODE	Encyclopedia of DNA Elements
EBV	Epstein-Barr virus
eQTL	expression quantitative trait loci
eSNP	expression single-nucleotide polymorphism
FDR	false discovery rate
GEO	Gene Expression Omnibus
GSST1	glutathione S-transferase theta 1
GST	glutathione S-transferase
GTEx	genotype tissue expression
GWAS	genome-wide association study
INDELs	insertion and deletions
LC-MS/MS	liquid chromatography–tandem mass spectrometry
LCL	lymphoblastoid cell line
LD	linkage disequilibrium
lncRNA	long noncoding RNA
NCBI	National Center for Biotechnology Information
NGS	next-generation sequencing
miR-eQTL	microRNA quantitative trait loci
miRNA	microRNA
PGRN	Pharmacogenomics Research Network
PharmGKB	Pharmacogenomics Knowledgebase
SNP	single-nucleotide polymorphism
sSNP	splicing single-nucleotide polymorphism
sQTL	splicing quantitative trait loci
TSS	transcription start site
UGT	uridine diphosphate glucuronosyltransferase
UTR	untranslated region
VIP	very important pharmacogene

8.1 OVERVIEW

DNA sequencing is an experimental process of determining the order of nucleotides in a given DNA molecule. Precise knowledge about the DNA sequence of entire genomes is paramount in identifying genes, transcripts, and proteins downstream, and consequently in elucidating biochemical processes taking place in a given organism. Until a decade ago first-generation sequencing was dominated by the chain termination method, developed by Fred Sanger [1], which generated detailed knowledge about the nucleotide sequence of many prokaryotic and several eukaryotic genomes, contributing to various genotyping and mutation discovery projects as well as assessing gene expression levels through serial analysis. The most spectacular achievement, however, was sequencing the entire human genome [2,3], which took a decade at cumulative cost of $2.7 billion [4] before it was finally completed in 2003. The subsequent arrival of next-generation sequencing technologies not only reduced the cost of sequencing and increased throughput but also opened a variety of applications not available to the traditional first-generation sequencing. It is through these applications that new-generation sequencing revolutionized research in genomics, epigenomics, transcriptomics, and metagenomics. In this chapter we discuss the current state of next-generation sequencing technology with a focus on second-generation methods and the available applications.

8.2 FIRST-GENERATION SEQUENCING: CHAIN TERMINATION METHOD

The chain termination method in its contemporary version, which uses automated fluorescent DNA sequencing equipment [5], relies on an in vitro DNA replication reaction, where, alongside normal reagents—single-strand DNA template, DNA primer, DNA polymerase, all four standard deoxynucleotides (dATP, dCTP, dGTP, and dTTP)—a small population of irreversibly blocked, fluorescently labeled dideoxynucleotides (ddATP, ddCTP, ddGTP, and ddTTP) is added to the reaction. The incorporation of a dideoxynucleotide into the newly synthesized chain

TABLE 8.1 Major NGS Applications

Area	Application Type	Read Assembly	Data Type
Genomic	Sequencing new genomes	De novo	Sequence
	Variant calling	Mapping	Sequence
Transcriptomic	Transcriptome discovery	De novo or mapping	Sequence
	Differential gene expression	Mapping	Read count
Epigenomic	ChIP-seq: protein-binding sites or histone modifications	Mapping	Read count
	DNA methylation	Mapping	Sequence
Metagenomic	Microbiome profiling	Mapping	Sequence
	Metagenomic sequencing	De novo	Sequence

terminates DNA replication because it does not have the required hydroxyl group in the 3′ position. As a result, the final mixture not only contains the population of full-length DNA fragments but, most important, it also contains all possible prematurely terminated subfragments, fluorescently labeled according to the identity of the terminating nucleotides. These subfragments are then ordered according to their size using capillary electrophoresis, a high-resolution separation method, and the final nucleotide sequence is determined from the fluorescent peak trace chromatogram.

Modern DNA sequencers based on Sanger method can run simultaneous electrophoresis in 96 or 384 capillaries, produce up to 1000 base-pair-long reads of very low per-base error of 1 in 100,000. Because of relatively long reads and very high accuracy, this method is still popular for single-pass sequencing of DNA regions shorter than 1 Kbp, which is relevant to the closing of gaps when genomes are sequenced with different technologies.

8.3 THE CONCEPT OF NEXT-GENERATION SEQUENCING

By the time the first draft of the human genome was published in 2001 [2,3], it had become clear that new, faster and cheaper, technologies would be necessary for the more in-depth knowledge needed to analyze genetic variants associated with inherited diseases or to design genome-specific therapies underpinning personalized medicine [6]. Subsequently, the National Human Genome Research Institute (NHGRI) introduced a series of "$1000 genome" grants to stimulate breakthroughs in sequencing technology, aiming to sequence the human genome at the cost of $1000, which led to the emergence of several commercialized methods collectively branded as "next-generation sequencing" (NGS).

Looking from today's perspective and judging by the sheer number of scientific publications that exploit NGS, one can say that the development of NGS technologies has indeed been very successful. Not only did the cost of sequencing become cheaper over recent years, but the whole field has become democratized with the arrival of personal sequencers, which are now affordable to large laboratories or medium-size academic facilities. Furthermore, NGS technologies have enabled many diverse applications to address important questions in genomics, transcriptomics, epigenomics, and metagenomics. Some of the most important applications are listed in Table 8.1 and will be discussed in more detail in later sections. First, however, we will discuss some technological aspects of NGS.

It appears that a generic NGS workflow has three major components: library preparation, sequencing, and subsequent data analysis, where the DNA sequencing component is highly technology-specific while both library preparation and data analysis are more generic and depend on specific applications. Looking at the current landscape of NGS technologies, it seems possible to divide them into second- and third-generation methods, where the former, unlike the latter, are unable to sequence a single copy of DNA molecule and require a library of fragmented and amplified DNA [7].

8.3.1 Second-Generation Sequencing

Second-generation sequencing (SGS) can be described as "massively parallel sequencing of high numbers of spatially separated, amplified, short DNA fragments." SGS is different from the first-generation chain termination method in that the latter is not massively parallel nor are the sequencing fragments spatially separated. Although several SGS technologies have been commercialized to a different level of success, here we will focus specifically on just four of them that currently stand out as the most popular. These are the Roche 454 pyrosequencing technology [8], currently applied in GS FLX Titanium and GS Junior systems; the Illumina "sequencing by synthesis" technology [9,10], applied in Genome Analyser as well as in HiSeq and MiSeq systems; the Life Technologies "sequencing by oligo ligation detection" technology [11], applied in SOLiD NGS systems, and Life Technologies' semiconductor sequencing technology [12], known as Ion Torrent, applied in its Ion Personal Genome Machine (PGM) and Ion Proton systems. Given the SGS definition presented previously, a generic SGS workflow consists of distinct steps, as presented in the following subsections.

8.3.1.1 *DNA Library Preparation*

A DNA library is a population of DNA fragments ready for sequencing. Depending on the application, fragments are either obtained by DNA fragmentation methods such as nebulisation, restriction enzyme digest, or sonication (most applications), or generated by PCR amplification (amplicon sequencing). The fragments are ligated to specific 5′ and 3′ adapters, as all SGS technologies require attachment of the fragments to a solid surface. The adapters provide a universal sequence for hybridization to the oligo-coated surfaces and provide further amplification and sequencing (to be discussed). Each sequencing platform provides its own library preparation kits, which are often tailored to specific applications.

8.3.1.2 *Spatial Separation of Fragments*

In order to sequence the fragment ends in parallel, one needs to separate them spatially. The Roche and Life Technologies platforms use microscopic beads that capture individual single-strand DNA fragments [8,12]. After emulsion amplification (to be discussed), the beads, coated with millions of identical DNA molecules, undergo spatial separation by random distribution either into a two-dimensional matrix of wells able to hold one bead only (Roche 454 and LT Ion Torrent platforms) or onto a glass surface to which they are made to bind covalently (LT SOLiD platform) [11]. Illumina separates single-strand DNA fragments by attaching them in a random fashion to a continuous flat oligo-coated surface provided by a glass flow cell [9,13].

8.3.1.3 *Clonal Amplification*

In order to detect sequencing signals, SGS methods require an *in vitro* cloning step to amplify individual surface-attached DNA fragments, so that sequencing of a single fragment will in fact proceed in a concerted manner on a cluster of identical molecules. The bead-attached fragments (Roche 454, SOLiD, and Ion Torrent) are amplified through an emulsion PCR process [14], where each bead, after capturing a single fragment, is inserted into an emulsion droplet containing all necessary amplification reagents. After the droplets are broken and after subsequent DNA denaturation, beads with millions of single-stranded DNA copies are spatially separated as mentioned previously. The fragments attached to the flat surface (Illumina) are subjected to a bridge amplification process [9,13], which results in the conversion of spatially separated DNA fragments into homogeneous clusters containing millions of identical fragments.

8.3.1.4 *Sequencing DNA Fragments in Parallel*

In this process, the order of the nucleotides in each DNA fragment, represented by homogeneous clusters of fragments situated either on beads or on a flat surface, is determined. The process constitutes the core of different NGS technologies. All four methods discussed here use sequencing-by-synthesis. Upon providing sequencing primers and other method-specific reagents, they monitor the process of incorporation of nucleotides into a newly synthesized DNA chain either via polymerization or ligation reactions. The **Roche-454** and **LT Ion Torrent** platforms both work by quantitatively detecting molecules released during the DNA polymerization reaction, where one pyrophosphate and one hydrogen ion are released for a single nucleotide incorporation. More specifically, Roche-454 technology detects occurrences of pyrophosphate through a cascade of enzymatic reactions where, in the presence of adenosine 5′ phosphosulfate, the ATP sulfurylase quantitatively converts pyrophosphate to ATP, which then acts as a cofactor for luciferase-mediated conversion of luciferin to oxyluciferin. The latter reaction generates light in direct proportion to the amount of ATP. All necessary reagents are available in each pico-litre well, which is connected via optical fiber to a photoelectric matrix able to convert light flashes into electric signals [8]. The LT Ion Torrent semiconductor sequencing technology, on the other hand, focuses on detecting changes in hydrogen ion concentration. The release of hydrogen ions during the DNA polimerization reaction decreases the pH of the solution, and such change is then detected by the ion-sensitive field-effect transistor situated directly under the well and converted directly into an electric signal. The layer of micro-wells is directly connected to the layer of ion sensors to make a single semiconductor chip [12].

Both of the above technologies record an event of nucleotide incorporation without detecting the nucleotide identity. The latter can be determined by a recursive sequence of cycles where only one type of nucleotide is supplied to all wells; the identity of wells showing the positive sequencing signal is recorded and finally the excess of added nucleotides is washed out. The next nucleotide type can then be added to repeat the cycle. In contrast, the other two technologies discussed here determine the identity of the incorporated nucleotides directly. **Illumina** runs the sequencing process in cycles—at the beginning of each cycle all four nucleotides, modified to contain specific cleavable fluorescent dyes as well as reversible terminators, are added. For each computationally determined cluster position, the identity of incorporated nucleotide is then recorded via capturing the emitted fluorescence upon laser excitation. The fluorescent labels are then cleaved away, the incorporated nucleotides deblocked and the free nucleotide excess washed away to enable the next cycle [15]. On the **LT SOLiD** platform the DNA-coated beads, which are covalently bound to the flat surface, are combined with universal primers, ligase enzyme, and a pool of octameric probes. Upon hybridization of a probe complementary to the DNA template in a position adjacent to the primer, the probe is ligated to the primer and the identity of nucleotides in positions 4 and 5 are determined from the fluorescent dye attached to the end of the probe. Upon cleavage of the dye-containing stretch of the last three nucleotides, the system is ready for the next sequencing cycle, which will determine the identity of nucleotides in position 9 and 10. The entire round of ligation-mediated sequencing cycles results in determining the identity of pairs of nucleotides every three nucleotides apart, beginning with positions 4 and 5. The whole process just described is performed five times, where each run is offset from the beginning of the preceding run by one base. The alignment of the five reads results in the full sequence of the DNA fragment, with the advantage that each base has been sequenced twice [11,16].

8.3.1.5 Third-Generation Sequencing

Third-generation methods (TGS), which are beginning to appear, focus on monitoring the natural synthesis of a single DNA molecule without the need for DNA fragmentation and amplification [7]. Library preparation will be greatly simplified and sequencing signals will be collected in real time during the DNA replication process. Although third-generation methods are being actively developed, they have not yet established themselves to the extent that second-generation methods have. However, two technologies have emerged as candidates for leading the field. Pacific Biosciences commercialized their PacBio RS system, which uses sequencing by synthesis and focuses on direct identification of the nucleotides incorporated by DNA polymerase during the DNA replication process. This is not dissimilar to some of the discussed SGS methods. However, two major innovations allow this technology to be categorized as third- rather than second-generation. First, unlike other methods, PacBio RS uses modified nucleotides that have fluorescent labels attached to the terminal phosphate group rather than the base, which allows monitoring of the DNA replication in real time as the fluorophore is cleaved naturally by DNA polymerase. Second, the sequencing takes place on SMRT cells, which are nanofabricated consumable structures patterned with 150,000 zero-mode waveguides of extremely small volume, each holding a single active DNA polimerase molecule immobilized in its detection zone. This enables recording of the sequencing signal from a single nucleotide incorporation using a single DNA template without the need for amplification [17].

Another emerging third-generation technology is nanopore, which uses a single protein channel embedded in an artificial lipid bilayer to monitor the sequence-specific voltage changes during DNA transport through the channel [18]. Although several different companies have been involved in pursuing this approach, it seems that Oxford Nanopore is currently the closest to commercialization [19].

TGS methods promise massive improvements, in comparison to SGS methods, that include higher throughput and faster sequencing speed, leading to faster turnaround, longer reads (at the level of tens of Kbp), small amounts of starting material, and lower cost [7].

8.3.1.6 SGS Sample Preparation

Although NGS technology providers have their own library preparation kits and often their own data analysis tools, here we refrain from describing those and concentrate instead on the generic principles that underpin the use of protocols and methods. Most of the genomic DNA library construction protocols follow a sequence of generic steps, including DNA fragmentation, end repair, adapter ligation, size selection, PCR enrichment, and validation. Most popular DNA fragmentation methods include ultrasonication (e.g., Covaris, Bioruptor) or nebulization. The end repair process consists of a sequence of enzymatic reactions that blunt the ends and provide complementary overhang for ligating adapters. The adapters contain specific sequences allowing for attachment to a provided surface, PCR-based enrichment, initiation of the sequencing process, and barcoding of samples to enable pooling of multiple DNA libraries. After adapter ligation, the library is purified, size-selected to narrow the range of DNA insert length, and amplified to selectively enrich DNA fragments, which contain ligated adapters. The library is then validated by checking the required concentration (e.g., Nanodrop, Qubit) and the library size profile (e.g., Bioanalyzer). Finally, multiple barcoded libraries can be diluted and pooled accordingly.

8.3.1.7 Applications

As we have already mentioned, NGS technology has three major components: library preparation, sequencing, and data analysis. Sequencing is the core of each technology and therefore the most stable, while library preparation protocols and particularly data analysis tools have been developed very dynamically over recent years to cope with the increasing number of NGS applications. This process makes it challenging for sequencing facilities to keep up with the speed of development, which includes introduction of novel or more cost-effective library prep protocols and a plethora of newly developed bioinformatics methods implemented in publicly available or commercial software packages.

There are many NGS applications that are now routinely used. The most common are presented in Table 8.1. As one can see, these can be clustered in several ways depending on a variety of factors. The first factor we discuss is the area of interest in the context of existing "omics." By ***genomic*** applications we understand the applications where biological questions refer to genomic sequence, be it the whole genome, the exome, which can be defined as a part of the genome that is transcribed to mature RNA, or any smaller custom-designed regions representing, for example, a panel of genes related to a particular disease. The questions may relate to sequencing entire new genomes de novo or identifying sequence variation in groups of individual genomes, exomes, or gene panels when compared to the existing reference DNA sequences.

A different family of applications relates to **epigenomics** and answers questions related to changes in the epigenome. Here, we are interested in changes to the function of the genome, rather than genome itself, which are manifested in chromatin structure alteration. This can be elucidated through ChIP sequencing (ChIP-seq) experiments, which combine chromatin immunoprecipitation with NGS to identify a genome-wide landscape of given transcription factor–binding sites or chemical modifications to histone proteins. Similarly, a genome-wide profile of DNA methylation can be determined through, for example, bisulfite sequencing. Contrary to genomic and epigenomic applications, the ***transcriptomic*** family of applications focuses on determining the state of transcriptome, the transcribed genome, to answer questions on genome-wide gene expression patterns, and quantification of differential expression between a number of different conditions, as well as discovery of unknown transcribed sequences, including noncoding RNAs. These can be addressed through RNA sequencing (RNA-seq) experiments where cDNA libraries constructed from total RNA are sequenced. Different library construction protocols allow for interrogation of coding RNA, noncoding RNA, or even micro RNA. ***Metagenomic*** applications concentrate on analyzing entire communities of organisms rather than individuals. By targeted sequencing of a reference gene such as 16SrRNA, followed by detailed analysis of sequences covering its hypervariable regions, one can get information on bacterial community phylogenic profiles. On the other hand, sequencing the entire DNA or RNA complement, known as environmental shotgun sequencing, can provide information on community gene content or gene expression profiles to address questions about biochemical processes going on in the bacterial community colonizing a particular ecological niche.

8.4 APPLICATION-INDEPENDENT DATA ANALYSIS

The initial data analysis steps are common to all applications. These include base calling, quality control, and read assembly. They are discussed next.

8.4.1 Base Calling

Since each of the SGS technologies uses a different method of detection of the sequencing signal, which is measured when a nucleotide is incorporated during the sequencing by synthesis, the process of converting such signal into a nucleotide base, known as base calling, is technology specific. The LT SOLiD is the only technological platform that does not perform base calling and provides the raw data in a *color space* rather than *base space*, where the sequence of colors corresponds to the sequence of tiled di-nucleotides [11]; however, for the sake of clarity we will assume that a generic SGS technology converts the sequencing signal into the *base space*. Furthermore, each technology provides a statistical model that allows for estimating the confidence in a given base call by calculating sequencing error that corresponds to the probability that the base call is incorrect. Such confidence is usually expressed in a per-base quality score, Q, equal to $-10*\log_{10}(\text{error})$ [20]. Consequently, Q30 corresponds to sequencing error of 1 in 1000; Q20 corresponds to the sequencing error of 1 in 100. The base-calling process is usually hidden and performed automatically with a platform-specific software and results in delivery of raw data in the form of read sequences, where each base has an associated quality score. These are usually, but not exclusively, provided in FastQ format.

8.4.2 Read Quality Control

The analysis of millions of raw reads is important for assessing the quality of the sequencing experiment. To this end, one can look, for example, at the percentage of base calls above certain per base quality threshold and assess whether that percentage matches the technology provider specification. The series of box-plots representing quality score distributions per sequencing cycle is also informatory. For some technologies, like Illumina, the quality of base calls is expected to deteriorate throughout the sequencing process, which results in lowering the mean quality value and increase of the variance; however, the speed with which such deterioration takes place reveals whether the experiment can be treated as acceptable or not. In the latter case the data can be rescued by trimming every read to remove a fixed number of bases from the 3′end. As each sample has millions of sequenced fragments it is expected that the base fractions do not change between sequencing cycles and reflect the sample genomic GC content. If this is not the case and a distinguished pattern can be seen on the base-fraction per sequencing cycle plot, this could be indicative of a contamination with a persistent sequence, e.g. sequence adapter. Another QC measure is a distribution of mean read-quality, which one should expect to have a narrow peak, strongly biased towards high Q values, without any multi-modality. Monitoring of a read duplication level reveals whether raw sequences are unique. If they are not it may suggest amplification artefacts during library preparation. All the above QC measurements are usually performed by the manufacturer software, but they can also be provided through standalone software such as FastQC (http://www.bioinformatics.babraham.ac.uk/projects/fastqc/).

Even if data quality is as good as suggested by the QC measures mentioned above, there will always be some proportion of "bad" reads, which either have low overall quality, contain adapter sequence or are duplicates, believed to be amplification artefacts. To this end the read filtering process can remove or trim the reads that contain the adapter sequence, e.g. using Scythe software (https://github.com/vsbuffalo/scythe), trim or filter out the reads whose overall quality is lower than a customizable threshold, e.g. using Sickle software (https://github.com/najoshi/sickle) and remove the duplicated sequences using Picard (http://picard.sourceforge.net) or SamTools (http://samtools.sourceforge.net) software. This is particularly important in case of sequencing the unknown genomes, where contaminated or low quality reads may lead to spurious read assembly.

8.4.3 Read Assembly

All existing NGS technologies provide the raw data in form of a vast number of short sequencing reads. Although the length of those reads and their number differ considerably depending on the sequencing technology, the individual reads are meaningless and need to be assembled into longer continuous stretches known as contigs in order to provide some meaning to what actually have been sequenced in a given project. Consequently, the initial part of data analysis of each NGS application, as specified in Table 8.1, is to generate a meaningful assembly that would constitute the solid base for downstream analysis. There are two ways of constructing the read assembly depending on whether the reference sequence is available or not [21]. If it is available, then the entire process is conceptually similar to assembling a jigsaw puzzle when we know what the final picture looks like. We can then map the jigsaw bricks into their proper location on the picture, without giving too much thought into whether the neighbouring bricks fit one another, and this mapping process is at the heart of the puzzle solving. However, if we do not know what the final picture looks like, the process is much more complex as we need to find the bricks that fit one another in a sensible way. This challenge is conceptually similar to the read assembly process in the absence of the reference sequence.

8.4.3.1 De Novo Assembly

The read assembly in the absence of a reference sequence, known as sequencing *de novo*, is typical of projects where genomes or transcriptomes of a given species are sequenced for the first time. At the time when the first-generation, chain termination method was a method of choice for genome sequencing, the *de-novo* read assembly process followed the "overlap-layout-consensus" paradigm [22]. First, reads would be subjected to exhaustive, "all against all" pair-wise sequence comparison, to identify pairs of overlapping reads as measured by fulfilment of some read overlap criteria. In the subsequent layout step, a basic assembly graph would be constructed where nodes correspond to reads and edges are overlaps identified in the previous step. The subgraphs consisting of uniquely overlapped reads would then be collapsed to form new nodes corresponding to contigs, where forking edges would mark contigs not uniquely connected indicating potential repeats. The objective of the layout step, is to simplify the basic assembly graph and to find the optimal assembly by constructing a path that visits each note exactly once, which is very difficult if numerous repeats are present in the graph. In the final process, the identified path is converted to a nucleotide sequence representing the consensus after mapping all contributing reads. The arrival of NGS technologies made the above assembly process very difficult to employ because of a much higher number of reads and far shorter read length. The assembly graphs constructed from the NGS reads became far too complex to resolve during the layout step. To tackle this problem Pevzner and coworkers [23] moved the assembly process from read space to k-mer space, where k-mer were short, fixed-length sequences obtained by hashing the reads (k base pairs long, where usually $k > 19$ and shorter than the read length). The assembly graphs were replaced with de Bruijn graphs where k-mers were nodes connected by edge if they overlapped by $k-1$ base pairs exactly, which means that the pair of adjacent, unique k-mers would be linked by a single edge. These graphs were much easier and quicker to construct, and the repeat structures easily identified. Currently, the most advanced *de-novo* genome assemblers such as Velvet [24], Euler-SR [25], ALLPATH [26] or Abyss [27] all use the de-Bruijn graph concept but differ in the way they handle paired-end information and sequencing errors [21].

8.4.4 Assembly Through Read Mapping

As seen from Table 8.1, most of the NGS applications rely on the knowledge of the reference sequence. The read assembly in the presence of such sequence, known also as read alignment or read mapping, is a process aiming to identify the location in the reference sequence where the particular read originates from. Rather than relying on standard sequence searching programs, which were originally designed to search for sequence homology between evolutionary related sequences, such as BLAST [28], various read-mapping software assume that potential mismatches can come either from species polymorphism or from sequencing errors. Consequently, the criteria for successful read alignment calls would be very stringent, usually allowing no more than a couple of mismatches per read. Although the process of mapping short reads to the reference genome seems conceptually simpler than the process of *de-novo* read assembly, to make such a process accurate and efficient requires complex computational algorithms. The first wave of computer programs, including MAQ [29], SOAP [30] and Mosaik (http://bioinformatics.bc.edu/marthlab/Mosaik/), uses hash-based algorithms, which build hash tables index's, either from the set of input reads or from the reference sequence, and then scan the complementary sequence, reference genome or input reads respectively, against said hash table. This accelerates the alignment by enabling fast access to the information on the location of subsequences in the reference. The second group of programs uses the Burrow Wheeler transform (BWT) concept, where the read sequences are transformed into BWT sequences, which enables a far more efficient way of indexing sequences for the purpose of alignment. The implementations of BWT-based methods in popular programs such as Bowtie2 [31], BWA [32] or Soap2 [33] are over one order of magnitude faster than hash table-based methods at the comparable level of accuracy, although they were reported to be less sensitive than the top hash-based aligners such as Stampy [34]. Moreover, they can use gapped alignment, which is particularly important if longer reads (>75 bp) routinely provided these days by various NGS technologies are aligned.

8.4.5 Sequence or Read Count?

After a read assembly is constructed, either *de-novo* or via read mapping to the reference sequence, we can divide the NGS applications into two groups where downstream analysis is either sequence-based or read-count based. In the case of the former, we actively use the sequence information available in the read assembly, for example, to annotate the newly assembled genome or to identify significant sequence variation in the assembly of multiplexed samples. The above applications stand in visible contrast to applications where downstream analysis relies entirely on the number of reads assigned to the genomic features present in the reference sequence. In the case of transcriptomic applications, such features are genes or transcripts and the corresponding read count relates to the level of gene or transcript expression, while in ChIP-seq applications the read count per fix-length adjacent bins is recorded in order to construct genome-wide profiles for identifying peaks corresponding to protein-binding sites [35].

8.5 GENOMIC APPLICATIONS

Genomic applications can be divided into two main groups: sequencing and annotating new genomes and identifying sequence variants in a number of samples.

8.5.1 De Novo Genome Sequencing

De novo sequencing of large genomes is still a formidable task usually performed by research consortia or very experienced research groups with substantial bioinformatic support. However, the arrival of NGS technologies democratized the field so that de novo sequencing of bacterial genomes can now be done routinely by small research groups equipped with a personal sequencer such as Illumina's miSeq. The cost of sequencing a bacterial genome at, say, 100× depth required for de novo assembly is well under £100 (about $162) per sample, and data analysis tools are easily available. The genome assembly described in the De Novo Assembly section usually leads to generating a number of contigs that may be hard to link given a particular sequencing technology because of repeat regions or sequence biases.

The quality of assembly may be measured with (1) number of contigs (the lower the value the better), (2) N50 value (the higher the value the better), defined as weighted median contig size so that half of the assembly is covered by contigs of size N50 or larger [36]. In the ideal scenario the assembly produces one contig, which covers the entire bacterial genome. The successful assembly is usually a combination of sequencing read length, sequencing depth, library insert length, and choice of assembly tool. The successful assembly must be annotated, a computational process that identifies genes within contigs either by homology searches or de novo gene prediction. It can be carried out using standalone software or, preferably, automated annotating systems such as BASys [37], IMG/ER (https://img.jgi.doe.gov/cgi-bin/er/main.cgi), PGAAP (http://www.ncbi.nlm.nih.gov/genome/annotation_prok/), RaTT [38], and RAST [39]. The typical pipeline uses several HMM (hidden Markov model) based gene predictors as well as BLAST-based homology searches. The identified coding regions are then annotated based on functional resources such as COG clusters (http://www.ncbi.nlm.nih.gov/COG/) or Pfam (http://pfam.sanger.ac.uk/), and downstream metabolic pathway analysis is performed using the KEGG database (http://www.genome.jp/kegg/). However, care should be taken when applying fully automated resources, as manual intervention is often required to improve performance [40].

8.5.2 Variant Calling Applications

Whether performing whole-genome sequencing or targeted sequencing, the techniques for variant calling are the same and rely on the information provided in the SAM/BAM file generated during the read-mapping procedure [41]: the list of alignments including mapped read IDs, their sequences, per-base qualities, mapped genomic coordinates, read directionalities, as well as read-mapping qualities, which relate to the probability of read erroneous mapping. The decision about calling a variant, such as a single-nucleotide polymorphism (SNP) or insertion and deletion (indel), has to be made after careful inspection of each position in the alignment and involves analyzing frequencies of mismatches to the reference and the associated qualities. To this end both the accuracy of the alignment and the accuracy of per-base quality scores are critical to successful variant detection. To reduce the uncertainty associated with variant calling, special care should be taken at various stages of the sequencing experiment and data analysis process [42].

To begin with, one should ensure enough sequencing depth during the sequencing process, as high depth increases confidence in a variant call and is critical for identifying rare variants. At the QC step, a stringent quality-based filtering should be applied, while at the read-mapping step multiple alignments should not be allowed, as both steps reduce the chance of spurious alignment. Prior to the proper variant calling procedure, the alignment data should be post-processed further. To this end, the list of the aligned reads should be sorted according to their genomic coordinates; the read or read pair duplicates, believed to be PCR enrichment artifacts, can be removed within Picard (http://picard.sourceforge.net) or SamTools [41] software. The reads mapped to more than one location should be removed, and the alignment around indels should be reassessed and, as it is likely to be inaccurate, corrected. This can be achieved with GATK software [43]. Last but not least, the quality scores should be re-calibrated to ensure that they reflect the true error rate rather than the error rate estimated based on technological uncertainties [44]. Such recalibration can be achieved with GATK software [43], where calculation of the real sequencing error rate is performed based on alignment stretches free from known SNPs and indels. Although the above preprocessing steps are widely used, at least one study analyzing human exome samples sequenced on the Illumina HiSeq platform found that the impact of data preprocessing on the accuracy of variant calling is much lower then anticipated [45].

The carefully preprocessed data can be used for variant calling or genotype calling. Here, variant calling refers to the identification of insertion, deletion (indel), or SNP at a given alignment position. Similarly, genotype calling refers to a description of a nonreference allele at a given locus in a given individual. Early SNP or genotype calling studies analyzed each sample separately and relied entirely on counting the abundance of alleles at a single site and applying a set of thresholds, for example minimum frequency of the minor allele in a heterozygous genotype. This approach encounters serious problems when applied to cases with low and moderate sequencing depth, as low frequency of one of the heterozygous alleles is likely to happen by chance, resulting in a spurious homozygous call. On the other hand, at low sequencing depth the accumulation of sequencing errors may lead to spurious heterozygous calls. Consequently, at low to medium sequencing depth, the SNP and genotype calls are associated with a high level of uncertainty and the methods based on applying fixed cut-offs are far from accurate because they are unable to quantify such uncertainties [46]. A range of probabilistic methods based mostly on Bayesian statistics have been developed that include popular software such as SamTools [41], GATK [43], or FreeBayes (https://github.com/ekg/freebayes). Here, the genotype calls are made based on posterior probabilities calculated from genotype likelihoods and assigned priors, using Bayesian formula. The genotype likelihood, which represents probability of observing sequencing data at a site given an underlying genotype can be calculated using base call uncertainties captured in recalibrated base qualities. The prior genotype probabilities can be enhanced using information available in SNP databases, such as dbSNP. These can be further improved if many individuals are analyzed together because allele frequencies estimated from merged datasets can be incorporated into priors.

Filtering of variant calls is a standard practice, as the variant caller–generated list is likely to contain a high number of false positives. Such filtering usually checks for deviations from Hardy-Weinberg equilibrium [46] and applies a set of thresholds for minimum read depth, minimum per-base quality, minimum distance from an indel, strand bias, and so forth.

8.5.2.1 Example

Biankin and coworkers [47] performed exome sequencing on the prospectively accrued clinical cohort of 142 patients to define genome aberrations in early sporadic pancreatic ductal adenocarcinoma (PDAC). They ran exome sequencing using both SOLiD and Illumina platforms to identify the genome-wide landscape of aberrations and to identify significantly mutated genes. The analysis of the informative subset of 99 patients with cellularity greater than 20% revealed 2627 high-confidence mutations, of which 2016 were nonsilent. The subsequent analysis of genes with nonsilent mutations that occurred in more than one individual cancer revealed that 16 genes were significantly mutated, half of which were already known (KRAS, TP53, CDKN2A, SMAD4, MLL3, TGFBR2, ARID1A, and SF3B1) and another half were novel mutated genes involved in chromatin modification (EPC1 and ARID2), DNA damage repair (ATM) and other mechanisms (ZIM2, MAP2K4, NALCN, SLC16A4, and MAGEA6). All of these genes except MAGEA6 had attributed confirmed or potential relevance when screened against a number of published experimental biological screens and are therefore good candidates for involvement in somatic driving events of carcinogenesis.

8.6 TRANSCRIPTOMIC APPLICATIONS

In **transcriptomic** studies, the aim is to quantitatively identify the RNA content in samples, usually with the intention of making comparisons between different conditions. Until recently the main technology for the transcriptome analysis was gene expression microarrays, which interrogate the mRNA population by hybridization to an arrayed library of probes. Although microarrays have been very successful, particularly in the analysis of differential gene expression, their use was limited to analyzing gene models that were already known and used for designing the interrogating probes. Conversely, no conclusions could be derived for a part of the analyzed RNA population that would not be captured by a given microarray, and so it can be noted that microarrays did not contribute much to broadening our view of the transcriptome landscape. This situation has changed with the arrival of NGS technology, and particularly its whole–transcriptome-sequencing application known as RNA-seq. Here, the entire RNA population can be interrogated with minimal losses. The reads that can be mapped to the reference genome or assembled de novo contribute to further analysis, but even the reads that fail to map can be investigated further in an attempt to assemble them to completely novel genes. Furthermore, not only can the reads be mapped to the existing transcript models; they also can identify novel splice junctions, putative exons, and noncoding RNAs, and they can be assembled to novel transcripts [48,49]. These make the RNA-seq an extremely powerful tool able to discover new transcriptomic features and consequently able to broaden our view of the transcriptome landscape. Despite the discovery power of RNAseq, it is often used in "conservative" mode when there is no interest in new discoveries, but even then RNAseq has strong advantages over microarrays because it can provide much higher dynamic range, sensitivity, and accuracy [50]. That claim, however, was strongly contested when a rich-content, human transcript array was developed [135].

8.6.1 Library Preparation

In order to perform meaningful RNA-seq experiments, the extracted RNA has to be converted to cDNA and the latter has to be processed further in a fashion similar to genomic DNA processing. The caveat of this approach is that ribosomal RNA (rRNA) which constitutes approximately 90% of total RNA, hinders the coverage of mRNA, usually the focus of the study. One way of dealing with this problem is to select for the "interesting" RNA, and this approach is taken when the poly(A) selection method is applied to capture the mRNA complement in eukaryotic organisms, benefitting from the fact that mRNA 3′ends are polyadenylated. Here, the poly(A)-containing molecules are captured using poly(T) oligo-attached magnetic beads; then the captured mRNA molecules are fragmented and the first strand of cDNA synthesized using reverse transcriptase and random primers followed by second-strand synthesis. Poly(A) selection is a very effective method of enriching mRNA, but it misses nonpolyadenylated mRNAs as well as noncoding RNAs. The other approach used, particularly when RNA is not intact or when polyadenylated species are not the only focus of the study, is rRNA depletion, using methods such as RiboMinus [51] or RiboZero [52]. The resulting rRNA-depleted RNA is enriched for both polyadenylated and nonpolyadenylated RNA, preprocessed RNA, tRNA, and numerous noncoding, regulatory species, which are often species of interest [53]. In such cases, rRNA depletion should be the method of choice; however, one should bear in mind that different library preparation methods may have different sequence coverage, which can introduce biases to mRNA expression quantification [53]. The enriched RNA, either via poly(A) selection or ribosomal depletion, needs be fragmented and converted to cDNA using reverse transcriptase and random primers. These are then processed via standard library construction protocols starting with the end repair step. The fragments are usually 100–250 bp long, although for some applications longer fragments are generated to help with resolving complex transcripts or with de novo transcriptome assembly.

8.6.2 Sequencing

RNAseq experiments are usually performed using short 75–150 bp reads. Although single reads of this length align well to the reference genomes and the resulting read counts provide a reliable measure of exonic expression, the paired-end reads are superior as they help to resolve complex transcripts containing shared exons (to be discussed).

8.6.2.1 Reference Sequence

The RNA-seq approach heavily relies on the existence of an annotated reference sequence given that, in order to quantify expression, one needs not only to assign reads to genes/transcripts/exons but also to calculate their corresponding read counts. If an organism under study has a genome sequenced, the genomic sequence will be available and most of the time the genomic annotations containing positions of genes, transcripts, and contributing exons will be known and available in genome annotation files, usually in GFF/GTF format (http://www.sequenceontology.org/gff3.shtml). The quality of such annotation, however, varies greatly between species and depends on the complexity of the genome and also on the resources put into the annotation process. Usually, as in the case for all major model species, the genome releases, which provide improvements to genomic sequence, are rare but the updates to genome annotation are frequent, as work on annotation improvement is constantly carried out. To this end it is important to realize that for data analysis purposes one needs to record not only the genome version but also the genome annotation release. If RNAseq of a nonmodel species is performed, one can potentially use a reference genome of a relevant model species, hoping that a high proportion of reads will align to the reference despite sequence difference. It has been demonstrated that such an approach works; however, both bias and error increase with the evolutionary distance between model and nonmodel species [54]. The alternative approach, particularly attractive if there is no obvious reference genome available, is to assemble the transcriptome de novo from hundreds of millions of reads pooled across all analyzed samples in a given project. Although at first sight it may seem that such assembly is no different from de novo genome assembly, there are important conceptual differences, which reflect the substantial differences in genome and transcriptome architectures [55].

First, the transcriptome assembly process is expected to end up with a high number of small, disconnected de Bruijn graphs, each one corresponding to a given locus and representing its transcript structure, while the genomic reads can be collapsed into a small number of large graphs representing chromosomes. Second, de novo genome assembly methods rely on the assumption that sequencing coverage (number of reads covering a single nucleotide) is approximately uniformly distributed alongside the entire genome. Consequently, sequence stretches of unusually high coverage are likely to be repeats while unusually low coverage is associated with sequencing artifacts [21]. However, the uniform coverage assumption does not hold for transcriptome assembly. Not only can different transcripts have coverage that differs by several orders of magnitude because of different levels of expression; read coverage may be uneven within a transcript because of sequencing biases. Third, alternative splicing and instances of overlapping loci add to the complexity of de novo transcriptome assembly.

All of these differences resulted in the emergence of transcriptome-specific assembly software such as Trinity [55], Oases [56], and transABySS [57], which has been reviewed and evaluated elsewhere [58]. Regardless of a method of assembly, the new transcripts need to have a functional meaning assigned, which is usually achieved by searching for sequence homology to the annotated transcript and peptide sequences present in various annotated sequence resources.

8.6.2.2 *RNA-Seq Read-Mapping Process*

As we have already mentioned, when discussing genomic read mapping, the standard genomic read aligners allow only near perfect matches. Consequently, when applied to RNA-seq data, the standard aligners do not align reads that span exon-exon junctions because many mismatches can be caused by intronic sequences in the reference genome, leading to biased downstream quantification of gene expression. To deal with this problem one can either extract a collection of transcript sequences from the reference genome and use them as reference for read mapping, or expand the reference genome by complementing it with a set of known exon-exon junctions (Mortazavi et al. [48], Wang et al. [50]). Both strategies, however, greatly limit the scope of RNAseq analyses as they rely entirely on incomplete exon libraries and preclude discovery of novel splice junctions and exons. The alternative, more adventurous, approach is to map the reads to the unannotated genome using splice-aware aligners able to map "junction reads" to the reference genome across splice junctions in the absence of genome annotation. This approach was taken by several groups and resulted in the emergence of several programs, such as TopHat [59], SpliceMap [60], MapSplice [61], GSNAP [62], and QPALMA [63]. Tophat maps the reads in a standard way, constructs putative exon models from the clusters of aligned reads, and puts aside the "unmapped" reads. It then enumerates all possible canonical splice junctions between the putative exon models and selects those that can be aligned to the "unmapped" reads [59]. SpliceMap dissects reads into halves and maps them separately; then it narrows down the possible location of a splice junction and identifies the correct junction using the canonical splice junction definition [60]. MapSplice, GSNAP, and Qpalma map reads allowing for long gaps that can correspond to introns; they then identify the correct splice junction position either (a) by optimization based on the score capturing the quality and diversity of the read alignment around the splice junction [61] or (b) by searching using splice site probabilistic models [62] or models trained using machine learning [63]. In their final identification of splice junctions, both Tophat and SpliceMap use the canonical splice junction definition according to which GT and AG are in the donor and acceptor sites, respectively, GSNAP and Qpalma use splice site models generated using databases of confirmed splice junctions, while MapSplice works without any preconceptions of splice junction architecture.

8.6.3 Transcript Reconstruction

The read alignment step is followed by the transcript reconstruction step where all possible transcripts in a given locus are enumerated. This can be reasonably straightforward if one wishes to rely on the current genome annotation provided within existing GFF/GTF files, or it can be very complex if instead of using incomplete annotation one wishes to assemble transcripts *ab initio* from clusters of aligned and overlapped RNA-seq reads, as proposed in software such as Cufflinks [64] and Scripture [65]. For example, in Cufflinks the aligned fragments, preferably represented as paired-end reads, are assembled within each locus separately, resulting in a collection of loci-specific overlap assembly graphs that are then traversed to resolve and enumerate individual transcripts. Scripture is consistent with Cufflinks in general methodological outline, but differs in algorithmic details.

8.6.4 Quantification of Transcript Abundance

The raw quantification of transcript abundance is done by counting fragments assigned to each transcript. This can become complex in cases when exons are shared between transcripts, as there may be fragments whose assignment to transcripts is ambiguous. In such cases the contribution of a fragment to a transcript may be evaluated using that transcript abundance. For example, when calculating abundances, Cufflinks [64] uses a statistical model where the probability of observing each fragment depends on the abundances of the transcripts the fragment can have been derived from. Since different samples can have a different number of fragments in the library, the raw counts need be normalized to allow meaningful between-sample comparisons. The common practice in early studies was to scale the raw counts by the library size expressed as total number of mapped reads [48,66]. To this end, the normalized transcript abundances are sometimes reported in FPKM units, defined as number of "fragments per kilobase of transcript per million" mapped fragments [64], which is a paired-end extension of an earlier single-end read RPKM concept [48]. FPKM can be considered a raw count scaled by library size and length of the transcript.

It was demonstrated, however, that such global normalization is affected by a small fraction of highly expressed transcripts, which leads to biases in estimates of differential expression [67]. Consequently, several more recent methods corrected the library size scaling factors to take into account that a high proportion of transcripts usually have zero counts; a small proportion of high-count transcripts accounts for a high proportion of counts; and a small proportion of transcripts show differential expression. For example, a popular upper-quartile normalization method [67] that scales the raw count by the upper quartile of all nonzero counts was demonstrated to remove the bias without introducing additional noise. The above methods have been reviewed and their performance evaluated elsewhere on both real and simulated data [68].

8.6.5 Differential Expression

Most of the existing methods for RNA-seq analysis of differential expression are parametric and provide pairwise statistical tests based on the assumption that read counts come from the negative binomial (NB) distribution. In an early RNAseq study, Marioni and coworkers [66] showed that variation among technical replicates can be successfully modeled with Poisson distribution. Later studies showed that modeling variation among biological replicates using a Poisson model leads to overdispersion, and therefore modeling biological variation with NB distribution is justified. Several NB-based methods have been proposed and implemented in differential expression analysis software such as CuffDiff [69], DEseq [70], edgeR [71], and BaySeq [72]. The assumption of NB distribution makes it difficult to deal with multifactorial experiments, as the use of analysis of variance (ANOVA), a standard way of analyzing multifactorial microarray experiments, is prohibited because the assumption of data coming from normal distribution is not fulfilled. Indeed, only few methods able to analyze RNA-seq multifactorial experiments exist, implemented in edgeR [71], DEseq [70], and BaySeq [72] software. The first two are able to analyze general multifactorial experiments using NB-generalized linear models while the third uses an empirical Bayes approach to detect patterns of differential expression across multifactorial experiments.

8.6.5.1 Example

In their classic paper on RNAseq, Mortazavi and coworkers [48] quantified a mouse transcriptome by recording the frequency of gene occurrence in each analyzed sample across three different tissues of brain, liver, and skeletal muscle, using the Illumina GAII platform and single-end 25 bp reads. Despite using poly(A) selection, they managed to dramatically improve the quality of gene models by identifying ~17,000 new features, including ~3000 extended or newly identified 3′ UTRs and ~3000 new or extended 5′ exons as well as ~600 new candidate transcripts. The discovery power of RNAseq was further demonstrated by its uncovering of evidence for 145,000 different splices. The authors introduced the concept of RPKM measure and discussed the observed background level. This early study clearly demonstrated the superiority of the RNAseq approach over microarrays and showed the richness of data that can be generated from simple transcriptomic experiments.

8.7 EPIGENOMIC APPLICATIONS

Epigenomic applications are different from the applications previously discussed. Rather then interrogating genetic information contained in a genome or related to gene expression quantification, here we are interested in chemical modifications of genomic DNA and histone proteins, whose complete record defines the epigenome. For the purpose of this chapter, however, we will also consider genome-wide distribution of binding sites for various DNA-binding proteins as an epigenomic application. Consequently, these applications interrogate not what is in the genome but how the genome is packaged and how accessible it is.

The NGS-based analysis of the distribution of a given histone modification or the distribution of a given protein-binding site makes use of chromatin immunoprecipitation (IP) pull-down to enrich the DNA fraction in question. The DNA is then sequenced using a NGS method and the entire procedure is branded as ChIP-seq [73]. The interrogation of DNA methylation state, on other hand, is often analyzed by combining NGS with bisulphite treatment, which is known as BS-seq [74].

8.7.1 ChIP-seq

To construct ChIP-seq libraries one needs to chemically cross-link DNA to its interacting proteins or the associated histones, and then sonicate the chromatin to short (approximately 100–300 bp) fragments. The "interesting" fragments are then immunoprecipitated using antibodies specific to the DNA-binding protein under consideration or to a specific histone modification before the cross-links are reversed to obtain the DNA fragment population associated with either a given DNA-binding protein or a given modified histone, respectively. Library construction is then completed by ligation of the DNA fragments to the sequencing adapters, enrichment by PCR, and size selection [73]. Usually, for every ChIP-seq library, one should construct a control library by fragmenting DNA but not proceeding to the IP step, proceeding to IP with no antibody, or proceeding to IP with nonspecific antibody such as IgG. Although using control libraries increases the cost of the experiment, it dramatically reduces the number of false positives that appear because of artifacts related to nonuniform fragmentation, copy number variation, nonspecific pull-down, read mapping uncertainty, and GC content–related sequencing bias [75]. The sequencing is usually done with 36–100 bp single-end reads, >5 M reads for a *Drosophila* genome, and >20 M reads per large mammalian genome, as recommended by ENCODE and modENCODE consortia [76].

Data analysis of ChIP-seq experiments relies on mapping the reads to the reference genome and subsequent identification of signals associated with protein-binding sites or attachments of modified histones. Usually, the aligned reads are counted over a number of bins covering the entire genome, and it is determined whether a given bin count is different from the background, where the latter is modeled using Poisson distribution or estimated from the control sample. Different, probabilistic, peak-finding algorithms have been implemented in many available and popular programs, such as Erange [48], FindPeaks [77], MACS [78], QuEST [79], Useq (http://sourceforge.net/projects/useq/), Homer (http://biowhat.ucsd.edu/homer/chipseq/index.html), CisGenome [80], Fseq [81], SISSRs [82], Swembl [83], PeakSeq [84], Qeseq [85], CCAT [86], ChipDiff [87], SICER [88], RSEG [89], TPIC [90], and W-ChIPeaks [91]. The performance of 15 of these algorithms was thoroughly compared, using novel protocols based on validation discriminant analysis using two validation datasets designed for algorithmic benchmarking of key histone modifications [85]. Peaks associated with transcription factor–binding sites are usually narrow while those associated with histones are, on the whole, much wider and their distribution and shape depend greatly on the specific histone modification. Consequently, peak-finding algorithms optimized for detection of TF binding sites do not perform well in identifying histone modification signals and vice versa.

8.7.2 DNA Methylation

Although the ChIP-seq approach can be used to analyze DNA methylation using either methyl-binding domains containing proteins [92,93] or methylated cytosine-specific antibodies [93–95], currently the preferred method for interrogation of methylated DNA fractions is bisulfite sequencing, known as BS-seq [74]. Here, the sequencing library is constructed by subjecting DNA to sodium bisulfite treatment, which converts unmethylated cytosines to uracil with no effect on methylated cytosines. The following PCR amplification converts uracil to thymine, which results in unmethylated cytosines being represented by thymines ($C \rightarrow T$) and methylated cytosines being represented by cytosines ($C^m \rightarrow C$). Consequently, the sequencing of bisulfite-treated libraries results in a clear distinction between methylated and unmethylated cytosines at a single base resolution; however, it does not distinguish between unmethylated cytosines and thymines. This makes data analysis difficult and requires algorithms specifically crafted for the analysis of bisulfite-treated samples. To construct a BS-seq library DNA is initially fragmented and the fragments are ligated to either (a) intermediate adapters or (b) methylated sequencing adapters [35]. The fragments are then denaturated and each strand is subjected to bisulphite treatment followed by PCR amplification. If procedure (a) is selected, sequencing adapters need be ligated to intermediate adapters; however, for procedure (b) the methylated adapters become the proper unmethylated ones.

The amount of required sequencing is much higher than is the case for ChIP-seq because sequencing the entire genome at a reasonable depth using paired-end reads is required. Data analysis is divided into two major steps: read mapping and finding the DNA methylation profile. For several reasons, the alignment of BS-seq to the reference genome is far more difficult than the alignment of untreated reads. First, the searching space is increased because both DNA strands are no longer complementary after the bisulfite treatment. Consequently, a given BS-seq read has an equal chance of coming from either a bisulfite-converted forward strand or a bisulfite-converted reversed strand, as well as from their reversed complements. Second, most of the BS-seq reads have reduced complexity because they are

C-poor. This is due to the fact that methylated cytosines occur nearly exclusively in CpG sequences, which account for less then 2% of di-nucleotides. Thus, most of the reads have C converted to T. Third, mapping reads to the reference sequence is asymmetric because T in BS-seq reads can map to both C and T in the reference sequence, while T in the reference can only map to T in the reads.

Because of these difficulties, the standard DNA read-mapping algorithms are not applicable to the BS-seq read-mapping problem. For this reason, several complex BS-seq mapping algorithms have been designed, implemented in software such as BSMAP [96], BRAT [97], MAQ [29], RMAP [98], BS Seeker [99], BatMeth [100], Bismark [101], seqemehl [102], and B-SOLANA [103]. A comprehensive performance assessment of several of those algorithms has been carried out [104]. Several programs for post-alignment analysis, including Kismeth [105], BISMA [106], and QUMA [107] were developed for locus-specific analysis while GBSA [108] software was developed for genome-wide analysis. The post-alignment GBSA analysis removes duplicate reads assumed to be PCR artifacts, and then calculates coverage at each cytosine site of interest, these including CpG for eukaryotic organisms as well as plant-specific sites such as CHG and CHH, where H can be A, C or T. Methylation signals are then scored at each cytosine site and the cumulative score calculated to analyze transcript features such as promoters, transcription start site regions, and first exon and intron, as well as entire gene bodies. Lastly, methylation domains can be identified in an annotation-independent manner using a scoring algorithm based on scanning the entire genome with a sliding window. The domains are then annotated using proximal genomic features available in genome annotation files.

8.7.3 Example

A good example of a powerful epigenomic study is the pioneering work of Barski and coworkers [73], who used Illumina-based SGS to generate a high-resolution map for the genome-wide distribution of 20 histone lysine and arginine methylations in the human genome. They identified the position and shape of each histone modification signal and showed that active promoters are characterized by high levels of H3K27me1 (single methylation at lysine 27 of histone 3), H3K36me3, H3K9me1, H4K20me1, and H2BK5me1 downstream of transcription start sites (TSS). This pattern can potentially be used to identify novel transcriptional units and to confirm TSSs.

By correlating histone modification patterns with gene expression data, Barski and coworkers found out that H3K27me2 and H3K27me3, respectively, correlate significantly with gene silencing. Moreover, they found that H3K9me3 and me2 have significant correlation albeit to much lesser extent. They also confirmed that single, double, and triple methylations of H3K4 correlate well with gene activation, as do H3K27me1, H3K9me1, H4K20me1, and H2BK5me1, while both H3R2me1 and H3R2me2 show a corresponding modest effect. Among other things, their data clearly showed that in the case of H3K79 single methylation is modestly associated with gene activation, triple activation is associated with gene repression, and double methylation shows no preference. The data also clearly demonstrated that ChIPseq is a very powerful method that provides far superior high-resolution data at a lower cost when compared to the traditional ChIP-on-chip approach, which relies on identification of the “chipped” fragments by hybridization to microarray rather than sequencing.

8.8 METAGENOMIC APPLICATIONS

All of the applications discussed so far apply in situations where the sequencing experiment is done using samples from separated known species. This implicit assumption allows us to assemble reads de novo to construct the unknown genome or to map them onto the known single-reference genome. Here, we will discuss a new situation where the sequencing experiment is performed using DNA harvested not from a single species but from the entire microbial community inhabiting a given ecological niche. NGS studies on microbial communities revolutionized and democratized microbial research and increased our understanding of microbial communities.

It has been demonstrated that there are ten times more bacterial cells in the human body than there are cells making up that body [109,110], which leads to the logical conclusion that microbial communities inhabiting the human body must have a pronounced effect on various human conditions. Indeed, altered microbial compositions in the human body have been linked to conditions such as obesity, vaginosis, caries, and inflamatory bowel disease [111–115], and this linkage has led to major research collaborative projects like the Human Microbiome Project and MetaHit whose aim is to analyze the composition and nature of various microbiota, as well as their variability within and between different subjects. Here, we will focus on two NGS applications: microbiome profiling by 16SrRNA gene sequencing and proper metagenomic sequencing of the microbial community metagenome.

8.8.1 Microbiome Profiling

Next-generation sequencing applied to targeted amplicon studies focuses on one or a few phylogenetic marker genes and provides a cost-effective culture-independent method to study the composition and diversity of complex microbial communities. The most widely used gene is 16SrRNA, an excellent phylogenetic marker because it consists of nine different variable regions flanked by conserved stretches where the former are used as markers while the latter facilitate the design of primers for PCR amplification of the variable regions. Several studies have advocated using different variable regions either separately or in tandem [116–118], and various primer pairs of different levels of specificity have been proposed [119,120]. The resulting amplicons are sequenced using NGS technologies of relatively long reads. After the initial filtering step, the sequenced reads can be used either to identify the composition of the microbial community through classification methods or to explore microbial diversity via phylogenetic clustering. For identification, reads can be assigned to different taxonomic units using the Ribosomal Database Project Classifier [121], a naive Bayesian classifier developed for classification of bacterial rRNA sequences into the Bergey bacterial taxonomy [122], without the need for sequence alignment. To explore diversity, the read multiple sequence alignment is usually constructed first, followed by read clustering into operational taxonomic units (OTU) that can be assigned to known taxonomic groups. Phylogenetic trees can then be inferred followed by the analysis of diversity within or between samples.

Pyrosequencing using the Roche 454 platform was initially the most successful because it provided long reads (longer than 400 bp) that could generate high-resolution results when identifying taxa at the species level. However, the pyrosequencing complex error model required strong noise reduction in order to decrease the number of false OTUs [123]. The GAIIx and HiSeq Illumina sequencers entered the race, but deteriorating read quality on the 3′ end was a source of poor accuracy and classification efficiency [117]. Nevertheless, it seems that new developments in sequencing chemistry for the Illumina miSeq and Life Technologies PGM platforms will allow sequencing of 2 × 300 bp reads and single-end 400 bp reads, respectively, which promises to shift microbial profiling toward low-cost personal sequencers.

8.8.2 Metagenomic Sequencing

Metagenomics studies the collective genome of a community of uncultured microorganisms. Rather than use a targeted amplicon approach, metagenomic studies focus on sequencing the entire DNA complement of a given microbial community. To this end these studies concentrate not on composition and diversity but rather on gene content and the functional potential of genes given a particular ecological niche.

During sample preparation, care should be taken so that extracted DNA is representative of all cells in the samples and that potential DNA contamination is kept to a minimum. This is particularly important if the analyzed community is associated with the host of a large genome, as the host's genetic material may be sequenced unnecessarily. Experimental techniques like fractionation and selective lysis are used to minimize host material contributions to the sample [124,125]. Sequencing is carried out using the same approach as for whole genome sequencing of a single species, and subsequently the metagenomic reads need to be assembled to contigs that are then subjected to downstream analysis, leading to functional annotation. As in the case of a single-species sample, assembly may be done by mapping reads to the reference genome or by assembling them de novo. Although mapping metagenomic reads to the reference sequence using software such as Newbler (Roche), Amos (http://sourceforge.net/projects/amos/), or Mira [126] is effective, it only works for the small proportion of reads that come from species whose genomes can be included in the reference sequence. More often than not, however, metagenomic projects use de novo assembly because constructing relevant reference sequences would be greatly incomplete and would seriously limit the scope of the analysis.

Prior to de novo assembly, it is important to clean the data from all known contaminating sequences by running sequence similarity searches—for example, removing host eukaryotic sequences [127]. The main difficulty with assembling metagenomic reads is that the reads are derived from a high number of different microbial species. Contigs generated with standard de Bruijn graph assemblers are usually prematurely terminated—rare *k*-mers generated from reads derived from less abundant species are often removed under the assumption that they represent sequencing errors. This will negatively affect the accuracy of downstream functional analysis. Common regions in different genomes further complicate assembly [128]. New de Bruijn graph de novo assemblers, such as MetaVelvet [129] and Meta-IDBA [130], have been generated specifically for metagenomic applications with the difficulties just mentioned in mind. Both produce significantly longer contigs and are able to reconstruct sequences for low-abundance species.

In a process known as binning, the assembled contigs are sorted into groups likely to represent a single genome or closely related genomes. This is done by clustering contigs based on their GC content and *k*-mers abundance distribution. The resulting genomes, represented by groups of co-binned contigs, are then functionally annotated [128]. If large contigs are produced, standard web-based genome annotation software developed for bacterial genome annotations, such as BASys [37] and RAST [39] can be used. Their main advantage is that they can perform many different analyses, such as homology searches and gene prediction, in a fully automated fashion. Shorter contigs can be searched for the presence of genes, by sequence homology searches (e.g., BLAST) against existing protein sequence databases or, failing that, using tools for *ab initio* gene prediction [127]. The latter approach, usually based on pattern recognition algorithms or supervised learning, is challenging because many open reading frames are partial and therefore may not be easily recognized by *ab initio* predictors. An excellent tool for the analysis is a web-based server known as MG-RAST [131], which accepts collections of assembled contigs or raw reads for providing the functional annotations.

8.8.3 Example

In a recent study which used metagenomic sequencing to investigate microbiota and its functional potential Wang and coworkers analyzed 16 samples collected from dental swabs and plaques representing four periodontal states [132]. The sequencing used the Illumina HiSeq2000 platform providing 2 × 100 bp paired-end reads. After screening out human DNA contamination and quality filtering, the paired-end reads were aligned into 140–194 bp fragments showing between-reads overlap in the range of 6–60 bp. Identification of 16S rRNA sequences was performed using a RDP classifier. The analysis identified 34 novel oral genera present in three or more individual samples. Moreover, a strong correlation between community structure and disease status was observed. Subsequently, the metagenomic read assembly generated contigs that were further functionally annotated using the KEGG database. Wang and colleagues' analysis revealed overrepresentation of functional genes and metabolic pathways in the microbiomes in periodontal disease, related mainly to bacterial chemotaxis, flagellar assembly, and toxin biosynthesis. The researchers suggested that periodontal microbes can adapt to subgingival niches by overrepresentation of genes that may facilitate microbial location, colonization, and invasion of host tissues.

BOX 8.1 Targeted Sequencing

More often than not in NGS applications, researchers are interested in sequencing of certain DNA regions rather then whole genomes. To generate the final DNA library, the genomic DNA must be reduced to include only the regions of interest, which increases the cost-effectiveness of a given project. One would argue that sample preparation for ChIPseq and RNAseq is a good example of genome/transcriptome reduction, as those applications use immunoprecipitation pullouts or poly(A) selection and ribosomal reduction, respectively, to retain the interesting DNA fraction and remove the unwanted sequences.

Here, however, we discuss approaches to targeted sequencing, known as sequence capture, that provide "target enrichment" of interesting genomic subregions by precise design based on knowledge of the whole genome sequence. Targeted sequencing approaches are particularly important where relatively small genomic subregions must be analyzed in a high number of samples. In this case the low cost of sequencing can leverage the high cost of sequence capture.

Several target enrichment methods have been proposed with the aim of maximizing capture accuracy, specificity, and completeness, and minimizing cost and sample preparation time. These can be grouped into three categories: hybridization capture, multiplex PCR amplification, and selective target circularization [133,134]. **Hybridization capture** relies on generating a library of hybridization probes designed to complement the targeted region of interest. These probes are then used as baits against the fragmented library generated from a genome sample in a given NGS technology–specific fashion by ligating specific sequencing and multiplexing adapters to enable multisample pooling. Hybridization can be done on a microarray, with the probes chemically attached to a solid flat surface, or in solution, with the probes attached to magnetic beads. After hybridization is completed, the excess material is washed away and the harvested genomic fragments are recovered in a process specific to a particular enrichment kit. "In solution" methods have gained popularity over recent years because of their lower cost and simplified workflow. Hybridization capture methods are easily scalable and demonstrate a high level of uniformity, which makes them particularly successful for targeting whole exomes. Ready-to-use solutions are provided by several vendors, the most popular being the SureSelect range from Agilent, SeqCap EZ range from NimbleGen, TruSeq Exome Enrichment Kit from Illumina, and Ion TargetSeq Exome Kit from Life Technologies.

Selective target circularization methods are conceptually different although the target fragments are enriched by hybridization to the library of probes. Here, however, the probes, known as molecular inversion probes, padlock probes, or selector probes, are composed of two oligos, complementary to two noncontiguous stretches of a target region, and a DNA linker attached to them in the opposite linear order. Circular molecules are generated by gap-filling ligation chemistry, which ensures that only perfectly hybridized fragments are circularized. These fragments are then amplified and finally the linear fragments are excised from the circular constructs. The latter are ready for sequencing provided that the DNA linker contain NGS method–specific sequencing adapters and sample barcodes. Selective target circularization methods are more specific than hybridization capture methods, but they are less scalable. The HaloPlex range ready-to-use solution from Agilent is an example of a very popular enrichment kit.

In **PCR enrichment** many PCR reactions are carried out to generate amplicons that cover targeted regions. Although conceptually very simple, this approach faces serious challenges because a very high number of PCR reactions usually have to be done in parallel. Several vendors offer ready-to-use kits for long-range PCR amplification, product purification, and normalization, such as SeqTarget from Qiagen. Multiplexed PCR kits allowing many primer pairs to be run in a single multiplexed reaction are also available—for example, Ion AmpliSeq by Life Technologies. High-throughput parallelized systems are available from Fluidigm (http://www.fluidigm.com/targeted resequencing.html) and Raindance (http://raindancetech.com/targeted-dna-sequencing/).

Targeted enrichment approaches have been used successfully in a variety of applications designed for enrichment of different targets. These applications may be divided into three groups, exome enrichment, enrichment of predefined gene panels, and custom enrichment.

BOX 8.2 Exome Enrichment Kits

Several solutions are available for exome enrichment, most of them based on hybridization capture. They include SureSelect from Agilent and SeqCap EZ from NimbleGen. Both are available in two forms, one that enriches human coding regions only and one that enriches both coding regions and UTRs. Other options include TruSeq Exome Enrichment Kit from Illumina and Ion TargetSeq Exome Kit from Life Technologies, both of which are comprehensive solutions for enrichment coding regions, UTRs and various noncoding genes; they are specific to Illumina and Ion Torrent NGS technologies, respectively. CDS-only exome enrichment solutions based on selective circularization or multiplexed PCR enrichment are also available. They include Haloplex Exome Kit from Agilent and Ion Ampliseq Exome Kit from Life Technologies. Both significantly reduce sample preparation time compared to hybridization capture. Exome sequencing has become very popular and contributes significantly to identification of the causative variants for Mandelian diseases.

BOX 8.3 Gene Panel Enrichment Kits

Several vendors offer enrichment kits for disease-specific gene panels. Currently, the most comprehensive of these come from Life Technologies, which provides several ready-to-use panels for Ion Torrent NGS based on their Ion Ampliseq^{TM} target selection technology, which uses multiplexed PCR enrichment. These include the Ion AmpliSeq Cancer Hotspot Panel, which provides hotspot regions including about 2800 COSMIC mutations in 50 oncogenes and tumor suppressor genes; the Ion AmpliSeq Comprehensive Cancer Panel, which provides exons in more than 400 oncogenes and tumor suppressor genes; and Ion AmpliSeq Inherited Disease Panel, which enriches more than 300 genes associated with more than 700 inherited diseases. These panels require between 10 and 40 ng of DNA, which makes them applicable to formalin-fixed, parafin-embedded (FFPE) samples.

Life Technologies also offers Ion Ampliseq Community Panels, which are designed by a consortia of experts working in a given field to provide either comprehensive coverage of mutations in notoriously difficult genes or comprehensive panels of genes related to a particular disease. Currently, two community panels are available: Ion Ampliseq BRCA1 and BRCA2 Panel, covering mutations in the two tumor suppressors implicated in breast and ovarian cancers; and Ion AmpliSeq Colon and Lung Cancer Panel, covering hot spots in 22 genes implicated in colon and lung cancers.

Four other community panels are currently under development. These are the Ion AmpliSeq AML Panel, which will enrich the coding regions of 21 genes implicated in acute myeloid leukemia; the Ion Ampliseq CFTR Panel, which will cover all exons, intron-exon boundaries, and UTRs of the cystic fibrosis transmembrane regulator (CFTR) gene harboring hundreds of mutations implicated in cystic fibrosis; the Ion AmpliSeq Cardio Panel, which will cover all exons and UTRs of 62 genes implicated in cardiomyopathies, channelopathies/arrhythmias, and structural heart defects; and the Ion AmpliSeq TP53 Panel, with will cover all exons and UTRs of the tumor suppressor TP53 gene, which is implicated in many human cancers and is notoriously difficult for probe design because of the presence of repetitive sequences. Of other vendors, Roche Nimblegen provides the hybridization capture–based Neurology Panel Design, which covers mutations in 256 genes associated with 87 neurological disorders; and the Comprehensive Cancer Design panel, which covers mutations in 578 cancer-implicated genes. Illumina provides the TruSeq Amplicon Cancer Panel, which covers mutations in 48 cancer-related genes.

BOX 8.4 Custom Enrichment Kits

Many vendors provide custom enrichment solutions where probes (hybridization capture and selective target circularization) or primer pairs (PCR enrichment) are designed for customized sets of genes and cover CDSs only or both CDSs and UTRs. They can be ordered and delivered as custom gene panels. Such solutions rely on web-based design tools such as SureDesign (Agilent, https://earray.chem.agilent.com/suredesign/), which creates probes for both SureSelect and HaloPlex target enrichments; the NimbleDesign tool (Roche NimbleGen, https://design.nimblegen.com/), which custom-designs SeqCap EZ Choice Libraries; the Ion AmpliSeq Designer tool (Life Technologies, https://www.ampliseq.com/), which designs Ion AmpliSeq Custom Panels; and DesignStudio (Illumina, http://www.illumina.com/applications/designstudio.ilmn), which designs probes for the TruSeq Custom Enrichment kit.

8.9 CONCLUSIONS

The variety of applications presented here clearly demonstrate the power and the breadth of next-generation sequencing technologies. The limitations of second-generation sequencing, however, impact read length and accuracy as well as library preparation workflows. It seems that widely anticipated third-generation methods may overcome at least some of these and generate far longer reads from a single DNA molecule. This would improve the read assembly generated either de novo or via read mapping and consequently affect the quality of downstream analyses as well as facilitate studies on structural genomic variants.

Second-generation sequencing not only revolutionized genomic research but also had a strong impact on development of other "omics" such as proteomics and metabolomics. To this end, it seems that integration of data generated through various "omics" technologies will pose a strong challenge for the future.

9.4.5 Neurological Complexes 171
9.5 Personalized Medicine 172
9.6 Conclusions 172
Acronyms 173
References 173

9.1 OVERVIEW

Differences between physiological states at the cellular level are reflected by the expression level and state of all proteins. Therefore, proteomics, which aims at this, can in principle provide the most relevant single dataset that characterizes a biological system [1]. Mainly for this reason, proteomics has had a tremendous impact in biological research over the last 15 years; specifically, cancer research has benefited from this biological research discipline [2]. Figure 9.1 is a “word cloud” generated by analysis of website HTML tags associated with proteomics; and it demonstrates where proteomic discoveries have been most employed to date—namely, cancer research, drug and drug target discovery, and biomarker research.

Initially, study of the proteome was attempted using mainly two-dimensional gel electrophoresis. However, nowadays most proteomic studies use mass spectrometry (MS). Using MS, and very small amounts of biological samples or biofluids which are highly complex, it is possible to quickly identify peptides by matching their fragmentation profiles with available sequence databases. This approach is based on extensive use of tandem MS. In this case, full-scan MS is carried out on intact molecular ions (proteins or peptides) that are then fragmented successively to produce fragmentation scans, which are the key to obtaining primary sequence information (MS^n scans) [3].

A typical proteomic workflow starts with the solubilization of proteins from a sample that can then be digested enzymatically or chemically into peptides (bottom-up analysis) or analyzed directly as intact proteins (top-down analysis). Normally, a bottom-up approach is used for the study of complex samples (whole tissues, biofluids, etc.) in a high-throughput manner. In this bottom-up approach, also known as “shotgun proteomics,” the identification of proteins is achieved by utilizing the combination of tandem MS (or MS/MS data) and database searching [4]. In this context, we can find programs such as SEQUEST, where experimental MS/MS data are compared to the predicted in silico-generated peptide fragmentation patterns.

In addition to SEQUEST, many other methods have been developed to improve this process, as several challenges associated with bottom-up proteomics are still to be fully resolved, including probabilistic scoring schemes [5], implementing additional search criteria [6], and the use of identified spectra to bootstrap the database search [7].

FIGURE 9.1 **Proteomics word cloud.** Tag words associated with "Proteomics" from websites found on the www are depicted according to their frequencies attached to webpage-associated information to calculate the font-sizes in the figure.

Currently, there is no public repository of proteomic data. However, it is expected that public repositories will be available in the future that will promote and reinforce the need for standardization of data formats, as well as increase the availability of proteomic data to other scientific disciplines.

The main advantages of the bottom-up approach include a higher resolution of peptides compared to proteins in the separation step as well as a high sensitivity, which is of great importance because proteins, in contrast to nucleotides, cannot be amplified. Furthermore, with the bottom-up approach it is possible to chemically modify peptides to improve their quantification. ICAT [8], ^{18}O labeling [9], and tandem mass tags [10] are suitable techniques for peptide-based methodologies such as MudPIT. However, the bottom-up approach also has certain limitations that should be taken into consideration, such as a loss of information because of limited protein sequence coverage by the identified peptides and the loss of labile post-translation modifications, which can be very important in biomarker research. Furthermore, there can be ambiguity in the identification of isoforms or conserved domains, which are sometimes found in many proteins because of the multiple origins of identified peptides.

Top-down methods are based on the study of intact protein masses and their fragments for identification. They have progressed mainly because of the development of fragmentation reactions, including electron capture dissociation (ECD) and electron transfer dissociation (ETD), which can yield a more complete backbone protein fragmentation with more sequencing information while retaining important labile post-translational modifications (PTMs) [4]. In this approach, proteins are not chemically or enzymatically digested and therefore it is necessary to analyze simpler, or "cleaner," samples for their successful analysis. Data analysis utilizes the expressed sequence tag (EST) or de novo methods [11].

The main advantages of the top-down approach are higher sequence coverage of target proteins and more accurate characterization of PTMs [12]. The more extensive sequence coverage of the top-down approach reduces problems associated with peptide-to-protein mapping and improves isoform identification, which is an issue for bottom-up approaches [13]. Top-down approaches also have more reliable protein quantification [14], where intact protein abundances are measured directly. However, there are some technical limitations of the top-down approach, and therefore both top-down and bottom-up approaches should be perceived as complementary. In particular, the separation of intact proteins before MS analysis is very challenging and rather limited, although recent studies [15,16] have used the top-down approach for complex mixture analysis. Furthermore, higher mass accuracy instruments are needed for analysis (FTMS and LTQ-Orbitrap).

Figure 9.2 summarizes the most common processes and workflows used in published proteomics studies. In this chapter, we cover the main methodologies used for sample preparation, separation of proteins using gel and non-gel-based methods and possible methods for the identification and quantification of proteins/peptides. Finally, considerations for data analysis and evaluation are discussed.

9.2 DATA ACQUISITION

9.2.1 Sample Types and Sample Preparation Requirements/Protocols

In a research environment, the collection of biological samples (tissues or biofluids) for proteomic studies can be less problematic (more controlled parameters and less time) compared to large clinical trials. However, with the increasing evidence that pharmacogenomics, biomarker discovery, and proteomics play an important role in disease characterization at different levels—from epidemiology and diagnostic and prognostic classification to response prediction—therapy-appropriate samples for molecular research have become essential [17]. This increasing demand for personalized medicine is now being recognized not only by the pharmaceutical industry, but also by regulatory agencies and the general public. Such approaches are highly dependent on accumulating enough biological specimens to validate any findings.

Internationally, it can be predicted that biological sample collection will become increasingly accepted based on an ever growing body of molecular information that aids in understanding the health benefits of undertaking

such studies. However, for some areas of research, such as genome profiling, the opposite might hold true because of regional legislation and reservations. Globally accepted standardization of appropriate procedures to routinely collect samples has helped in acceptance of pharmacogenomic applications in clinical trials [18]. The type of sample to be analyzed often directly influences which methods can be employed in proteomic downstream analysis. Table 9.1 lists a few advantages and disadvantages of the main sample types used in proteomics as well as selected generic protocols for sample handling and conditioning for MS-based analysis.

9.2.1.1 *Urine*

Urine is an ideal source for biomarker research aimed at clinical application because it can be easily collected in large quantities using noninvasive methods. Proteins in the urine are mainly composed of plasma proteins that have passed through the glomerular filtration barrier and proteins secreted from the kidney and urinary tract [19]. A protocol for urine collection has been published following the recommendations of the Human Kidney and Urine Proteome Project (HKUPP) and the European Urine and Kidney Proteomics, EuroKUP initiative (for further and more detailed information, see www.eurokup.org/sites/default/files/StandardProtocolforUrineCollection.pdf). Ideally, the sample is mid-stream of the second morning urine or morning random-catch urine. It is also recommended that urine samples be collected in sterile or clean urine collectors. The following protocol has been adapted from the literature [20].

1. Collect at least 3 ml of midstream urine per sample.
2. Immediately spin at 1000 × g for 5 min at room temperature.
3. Aliquot the supernatant into 1, 10, or 50 ml fractions (depending on downstream application) on dry ice.
4. Store aliquots at −80 °C ideally, or store them at −20 °C. Time until freezing should be limited to 3 h.

TABLE 9.1 Sample Source Advantages and Limitations

Sample Source	Advantages	Limitations
Urine	Easy and noninvasive collection, obtained in large volume	Fluctuation of protein concentration over time and according to renal integrity; presence of salts and proteins in low concentration
Plasma	Larger final volume of fluid after processing than with serum; more rapidly processed than serum; more stable than serum because of inhibition of coagulation cascade	Sample dilution in citrate tube; possible interference of EDTA with detection method
Serum	Established sample banks often composed of serum aliquots (retrospective studies), proteins, and peptides that "survive" to the clotting procedure exhibit stability that can be exploited in routine clinical applications	Presence of various products derived from coagulation cascade; biomarker with poor stability during coagulation process will not be detected in serum; possible influence of disease on coagulation process
Saliva	Easy and noninvasive sampling	Low volume collected; presence of many proteases and unspecific materials such as food residues or microorganisms; level of certain plasma proteins not reflected
Tissue	Whole biological systems analysis possible; scaleable	Sampling and quantities obtainable can be a problem; identification of interesting features can be hidden beneath high-abundance molecules

5. Thaw samples at 4 °C. If thawing and refreezing occur, always keep a record of this event. Avoid freeze-thaw cycles if possible or limit them to two.
6. Centrifuge at 1000 × g and 3000 × g for 5–10 min to remove precipitated material.
7. If necessary, measure total protein concentration or creatinine level and standardize by dilution in appropriate buffer.

Thereafter, preprocessing or solubilization of urine proteins ultimately depends upon the method of detection. Regardless of the method used, a clean-up or purification step is recommended to reduce the concentration of salt or other interfering compounds such as urea. Moreover, the depletion of human serum albumin can help to reduce the complexity of urine and improve the sensitivity of low-abundance proteins [21]. Methods for preprocessing urine samples for gel-based applications have been published [21], and there are methods available for non-gel applications (MALDI, LC-MS, and CE-MS) that readers are encouraged to review [20,22].

9.2.1.2 *Plasma*

Blood in general, and plasma in particular, has been the biofluid of choice for many proteomic studies, especially those aimed at biomarker research. The undeniable importance of blood is due to its function as a carrier for all molecules to and from all tissues and organs in the body. Plasma is collected in a tube containing anticoagulant—commonly EDTA, although citrate and heparin have also been used. It contains not only the traditional "plasma proteins," but also tissue proteins and numerous distinct immunoglobulin sequences [23]. However, because of the amount of information contained in this biofluid and a wide dynamic range of the present molecules (more than ten orders of magnitude in concentration) [23], analysis of all compounds in plasma is not possible with available technologies. For this reason, compound enrichment and/or depletion procedures are needed as sample preprocessing steps.

Therefore, preprocessing methods, such as centrifugal ultrafiltration, solid-phase extraction with its different formats, and organic solvent extraction, among others, are possibilities that readers are encouraged to review and test prior to a final experimental design [24]. Standardization of the preanalytical phase, including sample collection, sample preparation, and sample storage, is of paramount importance in all biofluids but especially in plasma, where differences in proteolytic activities during the preanalytical phase can have a substantial influence on the proteomic final results, possibly leading to inappropriate conclusions [25]. The following is an adapted protocol [26,27].

1. Collect blood samples in EDTA tubes.
2. Incubate vertically at 4 °C for 30 min and centrifuge at 3000 × g for 20 min at 4 °C.
3. Store plasma sample supernatants at −80 °C for further analysis.
4. The following steps (5–12) remove high-abundance proteins from plasma using the Multiple Affinity Removal column (10 × 100 mm column) and proprietary buffer system (MARS^{TM}, Agilent).
5. Equilibrate the column for 4 min at room temperature with a flow rate of 1 ml/min.
6. Dilute 200 μl of plasma with 600 μl of HPLC MARS buffer A.
7. Centrifuge diluted plasma through a Spin-X centrifuge 0.45 μm filter, 1 min at 16,000 × g to remove particulates.
8. Inject the diluted sample at a flow rate of 0.5–1 ml/min.
9. Collect the flowthrough fraction in the 10.5–14.5 min retention time range. This corresponds to the low-abundance protein fraction.
10. Dialyze the flowthrough fraction with ammonium bicarbonate and lyophilize. Store at −80 °C for later analysis.
11. Elute bound proteins by adding HPLC MARS buffer B at a flow rate of 3 ml/min for 7.5 min.
12. Resuspend lyophilized fractions in TEAB buffer and determine protein concentration.

9.2.1.3 Serum

While plasma is collected in a tube containing anticoagulant, serum is collected in a tube containing no additives (in some cases, a form of micronized silica can be used to promote clotting) [28]. The coagulation step has an effect on the composition of the proteins present in serum compared to plasma, which should be taken into consideration. The following is an adapted method [29].

1. Collect blood in a serum separator tube and allow it to clot for 30 min at room temperature.
2. Centrifuge for 10 min at 1000 × g.
3. Aliquot the supernatant serum before flash-freezing at –80 °C.
4. Thaw the serum aliquot by submersion in a water bath at room temperature and process as soon as possible. Note that the quality of the sample deteriorates with each freeze-thaw cycle.
5. Remove particulates by centrifugation at 10,000 × g for 10–15 s.

Regarding sample pretreatment, the challenges associated with serum are similar to those with plasma. Therefore, it is necessary to deplete highly abundant proteins and/or isolate and enrich low-molecular-weight proteins in order to detect candidate biomarkers and to avoid a loss of assay robustness and sensitivity.

9.2.1.4 Saliva

Saliva is an attractive biofluid for proteomic studies because of the abundance of proteins it contains, which can be very easily obtained inexpensively, safely, and noninvasively [30]. Many proteins contained in saliva have been shown to be of clinical importance [31]. As with other biofluids, standardization of saliva sample collection and pretreatment are needed to obtain reliable and significant results. The following is an adapted protocol [32].

1. Aliquot saliva samples into 330 μl fractions on ice.
2. Add protease inhibitors (aprotinin, vanadate, and PMSF or other cocktail) if required and store at –80 °C.
3. Omit step 2 if supernatant saliva needs to be generated. This is done by centrifugation at 2600 × g for 15 min at 4 °C, addition of protease inhibitors to the supernatant only if required, and storage of all fractions and the pellet at –80 °C.

9.2.1.5 Tissue

The proteomic study of tissue is a direct and very informative approach that is particularly useful for studying the pathophysiological events that take place in a diseased condition. From a biomarker perspective, the main limitation of tissue is that it is not generally accessible, especially from control or healthy organisms for monitoring purposes. In this chapter, we present a commonly used method for the bottom-up study of the tissue proteome. The main advantages of this protocol are that the protein digests that it obtains are free of nucleic acids and other cell components; it can be applied to samples containing high concentrations of detergent; and the sample concentration is kept high as there is no precipitation. This protocol is adapted from the filter-aided sample preparation (FASP) method [33].

1. Lyse cells or tissues in lysis buffer (i.e., 4% SDS and 0.1 M DTT, or 2% SDS and 0.1 M DTT, respectively, in 0.1 M Tris-HCl, pH 7.6 buffer) using a 1:10 sample to buffer ratio by sonication or blending; incubate at 95 °C for 3–5 min.
2. Sonicate to reduce the viscosity of the sample and disrupt DNA aggregates.
3. Centrifuge at 16,000 × g for 5 min to pellet unbroken cells and other aggregates.
4. Mix 1 mg of protein (approximately 30 μl) with 200 μl of 8 M urea in 0.1 M Tris pH 8.5 and concentrate in an Amicon (Millipore), Hydrosart (Sartorius), or Vivaspin (Sartorius) centrifugal concentrator at 14,000 × g for 40 min.
5. Repeat the dilution and concentration step with the retenate; discard the flowthrough.

6. Add 100 µl of 0.05 M iodoacetamide in 8 M urea and 0.1 M Tris pH 8.5; mix for 1 min at 600 rpm and incubate without mixing for 20 min.
7. Centrifuge filter unit at 14,000 × g for 10 min.
8. Add 100 µl of 8 M urea in 0.1 M Tris pH 7.9, and concentrate by centrifugation at 14,000 × g for 15 min. Repeat this step twice.
9. Add 100 µl of 50 mM ammonium bicarbonate to the filter unit and centrifuge at 14,000 × g for 10 min. Repeat this step twice.
10. Digest the proteins by adding 40 µl of 50 mM ammonium bicarbonate containing trypsin, with a recommended ratio of enzyme to protein of 1:100; mix at 600 rpm for 1 min. The peptide content can be estimated by UV light spectral density at 280 nm using an extinction coefficient of 1.1 of 0.1% ($g\,l^{-1}$) solution.
11. Incubate the unit in a wet chamber overnight.
12. Transfer the filter unit to new collection tubes.
13. Centrifuge the filter unit at 14,000 × g for 10 min.
14. Add 40 µl of 50 mM ammonium bicarbonate to the filter units and centrifuge at 14,000 × g for 10 min.
15. Acidify the sample with trifluoroacetic acid or formic acid and desalt the filtrate.
16. Desalt small amounts of digest for direct LC-MS analysis on StageTips or ZipTips.
17. Desalt large amounts of peptide mixtures for off-gel separation on SPE cartridges according to steps 18–25.
18. Place a 3 ml MILI-SPE extraction disk cartridge (C18-SD) in a 15 ml conical tube.
19. Add 1 ml of methanol and centrifuge at 1500 × g for 1 min.
20. Add 0.5 ml of 0.1% trifluoroacetic acid, 70% acetonitrile in water; centrifuge at 1500 × g for 1 min.
21. Add 0.5 ml of 0.1% trifluoroacetic acid in water and centrifuge at 1500 × g for 1 min.
22. Load the filtrate and centrifuge at 150 × g for 3 min.
23. Add 0.5 ml of 0.1% trifluoroacetic acid in water and centrifuge at 150 × g for 3 min.
24. Transfer the cartridge to a new tube, add 0.5 ml 70% acetonitrile in water, and centrifuge at 150 × g for 3 min.
25. The eluate contains desalted peptides.

9.2.2 Analytical Platforms: Separation and Detection Techniques

Proteomic workflows based on MS analysis are ideally suited to investigate large and complex protein networks and dynamic molecular interactions that modulate molecular, cellular, and physiological processes in an unbiased and systematic fashion [34]. However, more often than not methodologies prior to MS analysis are used—for example, to reduce the complexity of biological systems, or to render samples compatible with MS analysis. Polyacrylamide gel electrophoresis (PAGE), capillary electrophoresis (CE), and liquid chromatography (LC) are such strategies routinely used in the separation and analysis of proteins and peptides [35].

All of these methodologies have led to further development of instrumentations, novel methods in data acquisition, and bioinformatics data analysis software tools [4,36]. Individually, both gel-based and gel-free methods have unique properties that can complement each other. The modular setup of many of these separation and MS analysis tools allows various adaptations in a multitude of ways [37], and combinations can result in advantages in analysis of complex biological samples. This has been demonstrated in numerous studies [38]. Table 9.2 lists the most common platforms used in proteomic analysis.

9.2.2.1 Gel-Based Approaches

Separation of polypeptides is often needed prior to mass spectrometric analysis to reduce the complexity of or to establish a focus for the molecules of interest. A traditional approach in most biology labs involves the use of gel-based systems, using either one-dimensional or two-dimensional separations.

One-Dimensional

One of the most common laboratory practices involves the separation of proteins by their migratory behavior through a molecular mesh by applying an electric current. This is known as one-dimensional gel electrophoresis or 1D gel analysis; it was first introduced by Laemmli in 1970 [39]. This method gives information about the purity of protein samples, yield of fractionation techniques, and molecular size and relative quantity of individual proteins. Subsequent recovery of separated molecules enables further analysis, such as amino acid sequence determination and ultimately protein identification by MS [40].

A variety of gel formats are available. Large gels are mainly used to separate complex mixtures or for specific applications such as 2D-PAGE. Small gels, called minigels, are the mainstay of most proteomic applications. The benefit of small gels is that they are relatively quick to perform, easy to use, relatively cheap to run, and, most importantly, commercially available in precast formats. The modified protocol, shown next, which is mainly used for the separation of small proteins and peptides of less than 20 kDa, includes the necessary chemical modifications of proteins/peptides required for subsequent MS analysis [41], and involves the use of commercially available precast gels.

1. Add 15 µl Tris-Tricine loading buffer (2× concentrated, BioRad) to 15 µl of the sample.
2. Reduce by adding DTT (1 mM final concentration) and incubate for 10 min at 70 °C. Alkylate by

TABLE 9.2 Comparison of Platforms in Proteomics Research

Platform	Advantages	Limitations
1D gel-based	Inexpensive; simultaneous separation of many proteins; large mass range	Time-consuming; not suitable for analyzing smaller peptides, hydrophobic, very large or very small proteins
2D gel-based	Available in most protein labs; simple to perform	Time-consuming; no automation; problematic with hydrophobic proteins; mass range >10 kDa
DIGE	Higher reproducibility and quantification than 2DE	Expensive, same limitations as 2DE; requires specific imaging system
CE-MS	Automated; high sensitivity; multidimensional; low sample volumes required; reproducible; biomarker identification	Dynamic range restricted to proteins <20 kDa; protein identification not possible
LC-MS	Automated; multidimensional; high sensitivity	Quantitative analysis not simple; sensitive to interfering compounds; measurements of post-translational modifications requires additional tools
MudPIT	Automated; multidimensional; high sensitivity; detection of low-abundance proteins	Quantitative analysis not simple; sensitive to interfering compounds; high cost; additional steps
SELDI-MS	Simple to use; high-throughput, automated; low sample volumes required; enrichment of specific low-abundance molecules; biomarker identification; high dynamic range	Low–medium-resolution MS; limited information content; reproducibility and accuracy relatively low on older instruments; no protein identification; only relative quantification
ESI	Small sample volume; widely available	Very sensitive to interfering compounds
MALDI	High-throughput; high sensitivity and reproducibility	Machine-dependent; dynamic-range limitations; protein identification not easy
iTRAQ	Relative quantification of low-abundance molecules and hydrophobic samples; good reproducibility	Expensive; time-consuming; not easy to use
SILAC	Relative quantification, proteomics, and metabolomics; low-abundance molecules	Expensive; time-consuming; not easy to use; limited applicability
Label-free, SRM, MRM	Relative and absolute quantification; reproducibility	Expensive; software-dependent analysis; uncertain accuracy

adding 2 mM iodoacetamide (final concentration) and incubate 30 min in the dark. Quench by adding DTT to a final concentration of 50 mM. Heat samples at 95 °C for 5 min and load on 16% Tris-Tricine peptide or Tris-Glycine gel; run 2 h at 100 V (large gels) or 45 min at 200 V for minigels, or until the loading dye reaches the end of the gel.

3. Fix the gel by incubating for 30 min in 40% methanol, 10% glacial acetic acid.
4. Rinse gel with water.
5. Incubate in colloidal Coomassie for 2 h, gently shaking.
6. Destain 4 × 50 ml water 30 min each.
7. Excise bands on a light table and store at −40 °C.
8. Destain completely by first adding 50 µl 50 mM ammonium bicarbonate to gel bands and incubate for 30 min at 37 °C.
9. Add 100 µl acetonitrile and incubate for 30 min at 37 °C.
10. Remove liquid and repeat until the gel bands are completely destained.
11. Add 50 µl acetonitrile and incubate 10 min at room temperature to shrink the gel pieces; remove the liquid and air-dry the gel pieces for 10 min. Store at −40 °C if required.
12. Digest: reconstitute a vial of Trypsin (25 µg) in 250 µl 0.1% trifluoroacetic acid, dilute 15 µl of this stock in 100 µl cold ammonium bicarbonate buffer, add 5–10 µl to gel (10 for visible bands, 5 for clear regions) and add 50–100 µl ammonium bicarbonate to cover the gel pieces.
13. Incubate for 1 h at 37 °C, then overnight (up to 18 h) at 25 °C.

14. Add 100 µl acetonitrile and incubate for 30 min at 37 °C.
15. Spin and retain the supernatant in a new vial.
16. Add 50 µl 0.5% formic acid to the gel and incubate for 30 min at 37 °C; then add 100 µl acetonitrile and incubate for 30 min at 37 °C and combine supernatant with previous. Repeat this step.
17. Lyophilize the combined supernatant and store at −40 °C.

Two-dimensional and 2D-PAGE

Two-dimensional polyacrylamide electrophoresis (2D-PAGE), introduced in 1975 by O'Farrell [42], combines both isoelectric focusing (IEF) and 1D SDS-PAGE analysis. The first dimension separates biomolecules based on their isoelectric point (pI); the second dimension based on their molecular sizes [42]. This technique can, in theory, resolve any proteins present in a sample, including those containing PTMs or transiently expressed molecules [43]. Several disadvantages limit the general use of this methodology, such as dynamic range constraints, difficult to resolve proteins containing large hydrophobic regions, and often poor gel-to-gel reproducibility. Additionally, though high-resolution 2D-PAGE is capable of resolving 2000–5000 protein spots per gel [44], this is far below the expected several million potential isoforms in a complex biological system. The following generic protocol is a modified version of commercial IEF gel (IPG), 2D-PAGE kit (GE Healthcare), [45] and colloidal Coomassie staining [46].

1. Rehydrate a 24 cm IPG strip pH 3–11 nonlinear gradient with 450 µl of rehydration buffer containing 97 mM DeStreak (GE Healthcare).
2. Dilute the sample in a rehydration buffer containing 50 mM DTT and load onto the previously rehydrated IPG strip via cup loading.
3. Run the first dimension: the IEF can be carried out on an IPGphor II IEF system (GE Healthcare) up to a total of 42 kVh.
4. Second dimension preconditioning: equilibrate the strip in 10 ml of reducing SDS equilibration buffer 15 min at room temperature with agitation. Then eliminate the reducing solution and incubate with alkylating SDS equilibration buffer for an additional 15 min.
5. Second dimension: carry out on a 12% polyacrylamide gel at 2 W/gel (for overnight running) or after sample entry in the running gel (40 min); increase to 20 W/gel (max. 100 W) for in-day gel running, until the loading dye reaches the end of the gel.
6. Fix the gel for 1 h in an aqueous solution containing 2% (v/v) glacial acetic acid and 40% (v/v) methanol.
7. Stain for 1 h or overnight in 125 ml of a solution containing 20 ml colloidal Coomassie stock, 80 ml water and 25 ml methanol.
8. Rinse gel in an aqueous solution containing 5% (v/v) glacial acetic acid and 25% (v/v) methanol.
9. Destain for up to 1 h with 25% (v/v) methanol.
10. Cut spots of interest, digest according to the previous protocol, and analyze by MS and MS/MS.

DIGE

The difference gel electrophoresis (DIGE) method was developed to overcome some of the problems associated with 2D-PAGE, such as analytical variations, and to address the quantitative aspect of differential-expression experiments. This powerful quantitative technology has proven to be an important tool to assess and simultaneously measure with statistical confidence individual protein abundance changes for hundreds, if not thousands of intact molecules, in replicates over multiple variables. The technique uses up to three spectrally distinguishable fluorescent dyes (CyDyes Cy2, Cy3, and Cy5) in a multiplexing analytical run, where individual samples are labeled with one of the dyes, then combined, and then co-resolved in the same gel. Such a multiplexing step is beyond the capabilities of standard 2D-PAGE and allows for a direct quantitative comparison between samples analyzed on the same gel [47]. The following method has been adapted from the literature [48] using a commercial 2D analysis, a DIGE kit, and a software analysis solution (GE Healthcare). It includes further steps for alternative staining [49] and digestion [50] protocols.

1. Isolate proteins from samples, precipitate using the 2D clean-up kit, and resuspend in lysis buffer containing 7 M urea, 2 M thiourea, 4% CHAPS, 30 mM Tris-base; measure protein concentration.
2. Prepare CyDye reagents by adding N,N-dimethyl formamide (DMF) to each of three CyDye vials to obtain a final working concentration of 100 pmol/µl.
3. Spin down samples and prepare individual samples with 50 µg of protein extract.
4. Label individual samples with Cy3 or Cy5 dye by adding 2–4 µl (200–400 pmol) of either Cy3 or Cy5 working dilution for 30 min on ice in the dark.
5. Quench the reaction with 2 µl of 10 mM lysine for 10 min on ice in the dark.
6. For the internal standard, prepare a pool with 25 µg of protein extract from each individual sample. Label with Cy2 working dye on ice for 30 min in the dark and quench the reaction with 6 µl of 10 mM lysine for 10 min.
7. For each gel, combine the quenched Cy3- and Cy5-labeled samples and add 1/3 of the quenched Cy2-labeled pooled mixture.
8. Perform IEF and SDS-PAGE separation based on the protocol for 2D-PAGE, steps 1–5.
9. Image acquisition: for each gel, obtain the Cy2-, Cy3-, and Cy5-labeled channel image at excitation/emission

wavelength values of 488/520, 523/580, and 633/670 nm, respectively.

10. Analyze the images using DeCyder software (GE Healthcare) for spot detection and quantification and intergel matching and statistics: (a) DIA (differential in-gel analysis) for spot detection, which compares all three fluorescence images obtained from each gel and performs co-detection, background removal, and normalization; (b) BVA (biological variation analysis) for matching multiple 2D-DIGE gels, which provides statistical analysis of protein abundance changes; (c) EDA (extended data analysis) for advanced statistical analysis to generate the final list of candidate spots, PCAs (principal component analyses), and hierarchical clustering.
11. If MS analysis is to be performed, rerun samples without CyDyes (2D-PAGE, steps1–5) and stain gels using silver staining.
12. For silver staining, fix the gels in aqueous 50% (v/v) methanol, 5% acetic acid, for 20 min.
13. Wash gels in 50% (v/v) methanol for 10 min, then in water for 10 min.
14. Reduce for 1 min in 0.02% sodium thiosulfate (50 mg/250 ml).
15. Wash for 1 min in water twice.
16. Incubate with 0.1% silver nitrate (cold, 4 °C) (250 mg/250 ml) for 20 min.
17. Wash for 1 min in water twice.
18. Develop with 0.04% formalin in 2% anhydrous sodium carbonate (10 g/500 ml) in water.
19. Stop the reaction with 5% acetic acid.
20. Spot picking: match silver-stained gels against DIGE images and excise selected spots.
21. Reduce gel spots with 10 mM DTT in 50 mM ammonium bicarbonate.
22. Alkylate with 55 mM iodoacetamide in 50 mM ammonium bicarbonate.
23. Rinse gel pieces with 50 mM ammonium bicarbonate and acetonitrile and dry.
24. Digest proteins with trypsin at a final concentration of 7.5 ng/μl in 50 mM ammonium bicarbonate for 10 h at 37 °C.
25. Lyophilize supernatant and keep at 4 °C for later MS analysis.

9.2.2.2 *Non-Gel-Based Approaches*

Many biological samples contain a complex mixture of protein isoforms with or without PTMs, cleavages, and/or splice variants, as well as abundances that span a dynamic range of at least 12 orders of magnitude [51]. As a result, decomplexing of biological samples becomes a necessity for many applications, such as biomarker discovery. Gel separation, in particular 2D-PAGE, has, in principle, the capability but not the capacity to spatially resolve complex proteinaceous mixtures. Intrinsic limitations include problematic resolution of very small or very large proteins or physicochemical properties that are difficult to handle by gel analysis, as well as differences in abundance that can potentially mask proteins present in low quantities and also hinder the analysis necessary for biomarker research or functional characterization. Additionally, identification of proteins by in-gel digestion and extraction of resulting peptides or recovery of whole proteins after gel separation is far from straightforward and is often associated with considerable losses. As a consequence, alternative methods based on LC fractionation and separation techniques are increasingly employed [52].

CE-MS

Capillary electrophoresis (CE) is an analytical separation technique first mentioned in the scientific literature in the early 1980s [53]. CE separation is driven by an electric field applied to an open capillary tube; it can yield the rapid partitioning of hundreds of different molecules, which migrate at varying speeds through the system depending on charge and size [54]. The solutes can be observed by a detector as peaks, and quantitative information can be recorded, since the area of a peak is directly proportional to the concentration of the molecule. CE-MS, or the coupling of an MS instrument to CE, enables accurate determination of the mass of each peak in addition to the quantitative data. The coupling of CE and MS was first reported in the late 1980s [55] and has been shown to be an invaluable tool in biomarker discovery [56].

The interface of CE with an MS instrument can be done in a sheathless or sheath-flow setting online. Separated molecules are normally ionized after CE separation using electrospray ionization (ESI). The main benefits of this technique are that it can be used in fully automatic mode without compromising sensitivity and selectivity. The following generic protocol using a sheath-flow interface for the analysis of proteins/peptides with a molecular mass lower than 20 kDa was adapted from the literature [57]. For the analysis of intact proteins using CE-MS, readers are encouraged to look at alternative protocols [58].

1. Install the capillary tube (90 cm × 50 μm, uncoated fused silica capillary) in the CE instrument offline from the MS detector.
2. Condition the capillary with sodium hydroxide (1 M) at 50 psi pressure for 10 min, and then rinse the capillary with ammonium hydroxide (add 3.76 ml of ammonium solution at 25% and adjust the volume to 50 ml with deionized water), also applied at 50 psi for 10 min. Finally, rinse the capillary with running buffer at the same pressure for at least 20 min. After this conditioning step, connect the capillary online to the MS instrument.

3. If the CE is from Beckman, it must be run in "reverse mode" when connected to the MS system; therefore, an external detector adapter is necessary.
4. Before the injection of a sample, rinse the capillary with running buffer (add 10 ml of acetonitrile and 472 µl of formic acid and adjust volume to 50 ml with deionized water) at 50 psi for 2 min. Then inject the samples at 2 psi pressure for 99 s. Separate small proteins and peptides using a voltage of +25 kV for 30 min at a constant temperature (around 35 °C is initially recommended). Then, in addition to the voltage, separate at 0.5 psi for another 30 min.
5. After each sample run, rinse the capillary with deionized water (50 psi) for 1 min and then with ammonium hydroxide solution (50 psi) for 3 min. Finally, rinse the capillary with running buffer (50 psi) for 3 min.
6. Apply sheath liquid (add 15 ml of 2-propanol and 200 µl of formic acid and adjust the volume to 50 ml with deionized water) coaxially. The running speed of the sheath liquid is defined by the temperature and humidity in the laboratory (normally set at around 20 µl/h). Note that in this protocol no nebulizer gas is applied while the sample is being analyzed.
7. The ESI sprayer must be grounded to achieve electric potential zero and to set the electrospray interface potential at −4000–5000 V.
8. Record MS data at 400–3000 m/z for approximately 60 min, accumulating spectra every 3 s.

LC-MS

The most widely used MS technique today is LC–MS or HPLC–MS. This hyphenated method couples LC (usually a nanoflow HPLC system incorporating a switching valve) and MS, enabling separated biomolecules to be identified by their mass. A standard automated LC-MS system is made up of two three-way diverters, one inline with an autosampler and one switching valve inline with a column, to divert unwanted parts of the eluate to waste before it enters the MS system, the LC system, and the MS. This setup combines the separating power of the LC with the unparalleled capability of the MS to selectively detect and measure molecular parameters such as molecular weight and fragmentation pattern. LC-MS is invaluable for identity confirmation of known analyte molecules, and with modern MS machines it makes possible reconstruction of unknown entities from MS data through qualitative analysis [59]. The following method is a modified version of a published protocol [52].

1. Set up the LC system to consist of sample loop, trap column, and reverse-phase column suitable for nano-HPLC and proteomics analysis.
2. Load 20 µl of each pooled digested protein fraction into a 20 µl sample loop.
3. Inject the sample into the LC system on the trap column and desalt with 3% buffer B (0.1% formic acid in acetonitrile) for 10 min at 5 µl/min.
4. Run a gradient to 80% buffer B and acquire spectra in data-dependent mode in the 400–1800 m/z range. Select the five most abundant +2 or +3 ions in each MS spectrum for MS/MS analysis.
5. Set mass spectrometer parameters at capillary voltage 2.0 kV, capillary temperature 200 °C, and ion trap target value 10,000.

MudPIT

The standard approach for separating complex protein mixtures is 2D-PAGE or its variations. However, its considerable limitations have hampered general implementation of 2D-PAGE in proteomic workflows. These drawbacks include poor separation of highly acidic or basic proteins, a limited molecular mass range, exclusion of the majority of membrane proteins from analysis, gel-to-gel variations, and reproducibility issues. Since many membrane proteins are performing vital functions in cells, it is important to include this class of biomolecules in a global proteomic analysis of cellular systems. Multidimensional protein identification technology (MudPIT) was developed as a gel-free alternative to 2D-PAGE for analysis of both membrane and soluble proteins [60]; it uses column chromatographic separation of biomolecules prior to LC-MS analysis. The following protocol is an adaptation from the literature [61].

1. Chromatography setup is controlled by the Xcalibur interface on the tandem mass spectrometer.
2. Construct a three-phase inline column by packing an end-fitted capillary with reverse-phase resin, strong cation exchange resin, and another layer of reverse-phase resin in sequential order.
3. Load the sample offline onto the column and wash with 500 µl of buffer A (5% acetonitrile, 0.1% formic acid).
4. Install the column assembly in the LC-MS system.
5. Wash the column for 10 min with buffer A and apply a short pulse of water to it (50 µl).
6. Apply a shallow gradient to 84% of buffer B (95% acetonitrile, 0.1% formic acid).
7. Re-equilibrate the column with Buffer A (100%) for 10–15 min.
8. Add 50 µl of 100 mM ammonium acetate using an autosampler. Follow with a shallow gradient of buffer B to 80% acetonitrile, and re-equilibrate with 100% buffer A for 10 min.
9. Repeat step 8 nine times with increasing amounts of 50 µl ammonium acetate (200 mM, 300 mM, 400 mM, 500 mM, 600 mM, 700 mM, 800 mM, 900 mM, and 1 M, respectively).

10. Inject 100 μL 5 M ammonium acetate and elute with a shallow gradient of buffer B to 80% acetonitrile; re-equilibrate with 100% buffer A for 10 min.
11. Analyze by MS and MS/MS and process spectra as usual.

SELDI-TOF MS

Surface-enhanced laser desorption–ionization (SELDI) is a combination of solid-phase chromatography and time-of-flight mass spectrometry (TOF-MS) [62]. Different coatings on the chips allow the binding of various protein classes. ProteinChip arrays are available with different chromatographic properties, including reverse phase (H50), hydrophobic, hydrophilic, weak ion exchange (CM10/WCX2), and immobilized-metal affinity surfaces (IMAC3/IMAC30), or they are preactivated for the coupling of ligands. Thus, each analysis involves an in-built fractionation step, which reduces the sample complexity or enriches target molecules depending on the chip surface.

Sophisticated bioinformatics software tools are used for data processing once SELDI-TOF MS spectra have been collected. They are based on genetic algorithms, decision trees, and a unified maximum separability algorithm [63]. Commonly used are ProteinChip DataManager™, ProteinChip Biomarker Wizard™, and Biomarker Patterns™ (all from Bio-Rad). The following generic protocol is used in SELDI-TOF MS [63]. Note that the minimum sample requirement is 1–10 μg of the total protein per spot and 50–200 μl sample volume if a bioprocessor is used.

1. Assemble arrays in a bioprocessor.
2. Precondition the arrays using an appropriate buffer.
3. Add 50–150 μl of sample to each spot and incubate for 30 min with gentle shaking.
4. Wash three times with 150 μl binding buffer for 5 min with shaking.
5. Wash twice with 150 μl distilled water, 1 min per wash.
6. Remove the bioprocessor; invert and remove any remaining water.
7. Remove the reservoir from the bioprocessor.
8. Allow arrays to air dry.
9. Add twice 1 μl of 50% saturated SPA or CHCA matrix solution to the spot surface and allow to air dry in between.
10. The probes now are ready to be analyzed. If necessary, store the chips in a dark room at room temperature until processing.
11. Place the ProteinChip arrays in the SELDI-TOF MS (PBS IIc ProteinChip reader or ProteinChip System 4000, BioRad) and irradiate with a pulsed UV nitrogen laser.
12. Set the mass analysis range to be evaluated.
13. Adjust the laser intensity and other parameters.
14. Run instrument checks and calibrate the instrument.
15. Save the calibration curves (apply to spectra prior to analysis).
16. Load cassettes with chips into the protein chip reader.
17. Make test shots to optimize laser intensity and detector settings.
18. Incorporate laser intensity and detector settings into a spot protocol.
19. Assemble spot protocols into a chip protocol.
20. Assemble chip protocols into a cassette protocol.
21. Run the cassette protocol and collect data.
22. Normalize the data to a total ion current with an external value of 1.
23. View the spectra for high laser intensities for detection of high-molecular-weight species; set a cut-off mass range around 10 kD to exclude noise and leave the high-mass range unrestricted.
24. View the spectra for low laser intensities for detection of low-molecular-weight species; set a cut-off for exclusion of matrix noise between 1500 and 2000 Da.
25. Set noise definitions to desired settings.
26. Perform manual or automatic peak picking.
27. Perform statistical analysis.

9.2.3 Ionization Techniques

Matrix-assisted laser desorption-ionization (MALDI) and electrospray ionization (ESI) are capable of obtaining complete MS spectra, measuring the presence of molecules in complex mixtures and providing sequence information from biomolecules such as peptides. Both methods are considered “soft” ionization techniques because ions are produced and transferred into a gas phase usually indirectly, thereby enabling measurements such as time-of-flight (TOF). One of the main differences between the two is that ESI produces multiply charged ions, effectively extending the mass range of the analyzer, whereas MALDI generates many fewer multiply charged ions.

9.2.3.1 Electrospray Ionization

Electrospray ionization (ESI) produces a fine mist at the end of a capillary (e.g., chromatography column), which is aimed at an inlet in the mass spectrometer. Liquid is removed via heat and/or collisions with inert gases. Ions are produced by application of a high voltage between the emitter at the end of a capillary and the start of the mass spectrometer [3]. The most practical feature of ESI is that it generates multiply charged ion species [64] and therefore considerably extends the dynamic range. Coupling to a low flow-rate chromatography system can improve the sensitivity of this technique and enables multidimensional online separation and therefore expanded protein and peptide profiling [65]. The following method is an adaptation from the literature [66].

1. Load 10 µL of each pooled digested protein fraction into a 20 µL sample-loop.
2. After injection, trap the sample on a trap column and desalt with 3% mobile-phase B (80% acetonitrile with 0.1% formic acid) for 10 min at 4 µL/min.
3. Start the nano-HPLC gradient elution and acquire spectra in data-dependent mode in the 400–1800 m/z range. Select the five most abundant +2 or +3 ions of each MS spectrum for MS-MS analysis.
4. Alternatively, use a syringe pump to continuously feed the sample.
5. Use common mass spectrometer parameters: 2.0 kV capillary voltage and 150–200 °C capillary temperature.

9.2.3.2 Matrix-Assisted Laser Desorption Ionization

Matrix-assisted laser desorption ionization (MALDI) requires a laser energy-absorbing matrix that rapidly sublimates into the gas phase and transfers some of the energy to an analyte, which also undergoes sublimation. During this process $[M+H]^+$ ions of analyte in the gas phase are formed by ion–molecule reactions [3]. This ionization process necessitates several hundred laser pulses to obtain an adequate signal-to-noise ratio for ion detection; therefore, low shot-to-shot reproducibility and sensitivity to sample preparation methods are the main limitations [67].

MALDI has given rise to a number of derivatives, such as SALDI [68] and DIOS [69], which use porous graphite and silicon instead of a matrix and have been shown to have a higher tolerance toward detergents and salts. AP-MALDI, or atmospheric pressure MALDI, is a hybrid system that allows easy interchange between MALDI and ESI sources [70]. MALDI has also led to the development of SELDI technologies [71], in which a chromatographic functionality is embedded in the plate surface itself. It has also led to the development of material-enhanced laser desorption/ionization (MELDI), in which various derivatized carrier materials are used to batch absorb biomolecules similarly to the SELDI IMAC protocol [72].

The following generic MALDI protocol has been adapted from the literature [48].

1. Redissolve the dried samples in 10 µl of matrix solution—usually either α-cyano-4-hydroxycinnamic acid (CHCA) or sinapinic acid (SPA) dissolved in trifluoroacetic acid acidified acetonitrile.
2. Deposit 0.6 µl of the solution on the MALDI target plate.
3. Allow the sample-matrix mix spots to dry at room temperature.
4. Analyze the samples on a MALDI-TOF/TOF mass spectrometer.
5. Acquire MALDI-MS spectra by averaging 400 individual spectra in positive ion reflector mode at 50 Hz laser frequency at 800–3500 m/z. Perform internal calibration of the MALDI-MS mass spectra using the two trypsin autolysis ions at m/z 842.510 and m/z 2211.105.
6. Obtain MALDI-MS/MS spectra by averaging 800 individual spectra from precursor ions with intensity >1500 in the MALDI-MS spectra.
7. Perform automated analysis of the mass data using, for example, flex Analysis 2.2 software (Bruker) to obtain peptide (MALDI-MS) and precursor (MALDI-MS/MS) m/z values.

9.2.4 Identification of Peptides or Sequencing MS/MS

MS scans usually provide a rich source of information for peak patterns, distribution, and quantitation. However, the identification of peaks by sequence determination requires additional steps, such as collision-induced dissociation (CID) using atom bombardment or energy transfer dissociation (ETD). The fragmentation pattern of such MS/MS scans can be used to mathematically reconstruct a probable amino acid sequence by database matching associated with a protein [73]. A single experiment on a modern mass spectrometer can potentially generate tens to hundreds of thousands of MS/MS scans for thousands of peptides, providing unparalleled efficiency in potential peptide identification [74]. It is therefore required that the sequences be precisely determined with a minimal error rate [75]. Because of the sheer amount of data generated in a typical MS experiment, this process has an absolute requirement of full automation by in silico analysis.

Many software solutions are available to perform MS and MS/MS data processing using sophisticated algorithms and scoring schemes [76]. However, raw data formats are very often vendor-specific and the source data must be converted to a format that can be read by third-party applications while simultaneously retaining as much of the spectral information as possible. This requirement has led to the development of source data standards such as mzXML [77], mzData, and the newer mzML standard [78]. Both PEAKS [79] and MASCOT [80] can accept most MS data formats having to convert the data.

The following is a generic protocol that requires adjustment for a specific instrument [81].

1. Prepare peptide samples by trypsin digest and lyophilize.
2. Prior to analysis, calibrate the instrument using a standard calibration mixture.
3. Check the performance of the instrument with multiple LC-MS/MS analyses of 10 fmol BSA.
4. Resuspend peptides with 30 µL of 0.5% formic acid and incubate for 10 min at 25 °C with shaking.
5. To neutralize the pH, add 15 µL of 0.4 M ammonium bicarbonate and incubate for 10 min at 25 °C with shaking.

6. The resuspended peptides are now ready for LC-MS/MS analysis.
7. Use as mobile-phase A (water with 0.1% formic acid) and mobile-phase B (80% acetonitrile with 0.1% formic acid) for reverse-phase chromatography.
8. Before sample injection, equilibrate the trap column with 100% mobile-phase A and the analytical column with 5% mobile-phase B.
9. Load 40 µL of each peptide sample using an autosampler and desalt on a trap column (0.3 mm id × 5 mm) with a flow of 25 µL/min mobile-phase A for 5 min.
10. Switch the valve to bring the trap column online with the analytical column.
11. Start MS acquisition (for 35 min).
12. Start a gradient elution of the peptides at a flow of 0.3 µL per min on the analytical column, 5–40% mobile-phase B over 30 min, then wash up to 85% B for 5 min, repeat for another 5 min at 85% B, and re-equilibrate at 5% B for 15 min.
13. Use a database search engine such as MASCOT (Matrix Science), OMSSA, or ProteomeDiscoverer (ThermoFisher) with the appropriate reference database.
14. Process MS data using, for example, BioWorks 3.2 (ThermoFisher) to create a peak list file and submit to a MASCOT server for iterative searching on a protein sequence database.
15. Set acetyl (protein N-terminus), carbamidomethyl (C), and oxidation (M) as variable modifications, a peptide mass tolerance of ±20 ppm, and a fragment mass tolerance of ±0.5 Da; allow for a maximum of two missed cleavages.
16. Determine false discovery rates by reverse database searches and empirical analyses of the distributions of mass deviation. MASCOT ion scores can be used to establish score and mass accuracy filters.

9.2.5 Quantitative Approaches

Quantitative proteomics is a crucial technology for understanding biological systems, from protein expression changes to protein modifications associated with molecular pathways, biological processes, and disease conditions. Most quantitative proteomic experiments use isotopic or isobaric labeling strategies, which can then be differentiated by MS analysis. Relative quantitation methods (SILAC, ICAT, and iTRAQ) are generally used for comparisons of protein or peptide abundance levels between samples, while spiking unlabeled samples with known concentrations of isotopically labeled synthetic peptides can result in absolute quantitation of target peptides (SRM, MRM). Label-free methodologies are also useful for both relative and absolute quantitation, though they are profoundly more complex than protein and peptide identification.

9.2.5.1 ICAT

The isotope-coded affinity tag (ICAT) method was originally developed to reduce sample complexity and identify low-abundance proteins and peptides in complex samples [8]. ICAT tags originally consisted of a sulfhydryl-reactive chemical cross-linker, which can react with free thiols on cysteine residues, an 8-fold deuterated (d8) or light (d0) linker region and a biotin group. The proteins are then passed over immobilized avidin, which binds to the biotin tag and thereby purifies the labeled proteins from the sample. After this purification step, heavy (d8) and light (d0) samples are combined and analyzed for relative quantitation by LC-MS and identification by MS/MS.

Because cysteine residues are not present in all proteins, this methodology does not result in global labeling and therefore is an intrinsic approach to reduce sample complexity. However, this can also pose a problem if the target proteins contain very low levels of available reactive groups. Therefore, the difference in amino acid availability should be considered when determining the right isotopic labeling method quantitative proteomic analyses [82]. Modified ICAT tags were also developed that contain ^{13}C instead of deuterium to avoid the problem of partial peak partitioning during LC separation [83]. The following protocol is an adaptation of a previously published application [84] that uses the ICAT labeling kit (Invitrogen).

1. Denature the sample by incubation at 95 °C.
2. Add a reducing agent such as DTT to a final concentration of 5 mM and incubate at 37 °C for 20 min. Precipitate the proteins by adding 6 to 7 volumes of cold acetone and incubate at −20 °C for at least 1 hour. Spin the sample, dry the pellet, and resuspend in a minimal amount of 5 mM Tris–HCl, pH 8.3, 10 mM EDTA.
3. Dissolve the ICAT reagent in 20 µl of acetonitrile per tube. Add the sample to the ICAT tube at a minimum concentration of 6-fold molar excess of ICAT reagent. It is important that the ICAT reaction be conducted in as small a volume as possible, ideally less than 150 µl per tube.
4. Incubate the reaction at room temperature in the dark for a minimum of 2 h.
5. Check the ICAT label incorporation on SDS–PAGE, which will result in a shift in the protein bands.
6. Stop the reaction by adding 5 mM DTT and incubate at 55 °C for 20 min.
7. Combine the ICAT-labeled samples at the desired ratio, ensuring that the final urea concentration is less than 1 M.
8. Trypsin-digest proteins at a 1:50 (w/w) ratio (trypsin/sample) overnight at 37 °C.
9. Remove excess unreacted ICAT tags by cation exchange separation prior to avidin purification.

10. Clean the ICAT-labeled peptides by avidin column chromatography according to the manufacturer's protocol.
11. Cleave off the biotin moiety by adding 95 μl cleaving reagent A and 5 μl cleaving reagent B to each avidin-purified fraction and incubate at 37 °C for 2 h.
12. Quench the reaction by adding 8 μl 0.2–0.4% acetic acid to each fraction, mix and centrifuge. Transfer the supernatant to a new vial for LC-MS/MS analysis.

9.2.5.2 iTRAQ

iTRAQ uses isobaric tags, originally termed tandem mass tags, that have identical masses and chemical properties; therefore, heavy and light isotopologs co-elute during LC separation. These tags are subsequently removed from the peptides during the LC-MS/MS run by CID [10]. A clear advantage of these isobaric mass tags is the flexibility they provide in choice of labels as well as their multiplex capabilities. Commercially available tags—for example, TMT™ or iTRAQ™—offer the simultaneous analysis of 4, 6, or 8 biological samples. The basic components of all isobaric mass tag reagents are (1) a mass reporter (tag) containing a unique number of ^{13}C substitutions and (2) a mass normalizer with a unique mass used to make all tags equal in mass. Additionally, isobaric mass tags possess a reactive moiety that cross-links to a specific chemical group in a polypeptide—for example, primary amines or cysteines—and are designed to fall apart at a specific linker region during high-energy collision-induced dissociation (HCD). These different-sized tags are then analyzed by LC-MS/MS, resulting in concurrent peptide identification and relative quantitation. Furthermore, because MS/MS is required to detect the isobaric tags, unlabeled peptides cannot be quantitated. The following protocol is an adaptation of a previously published method [85] and uses the iTRAQ labeling kit (Invitrogen).

1. Extract proteins from tissues, cultured cells, or biofluids in a homogenization buffer of choice (200 μl) and sonicate for 2 min.
2. Spin at 12,000 × g to pellet insoluble materials.
3. Determine the total protein concentration.
4. (Optional) Clean up the sample by acetone precipitation: add 6 volumes of cold acetone to the cold sample tube, mix and incubate at −20 °C until a precipitate forms (about 1 h); then spin the sample to pellet the proteins, decant the acetone, and air dry.
5. To each tube containing 5–100 μg of sample, add 20 μl of a resuspension buffer of choice.
6. Add 1 μl of the denaturant solution with a final SDS concentration of 0.1%, and mix by vortexing.
7. To each sample, add 2 μl reducing reagent, mix, and incubate at 60 °C for 1 h; then spin and add 1 μl cysteine-blocking reagent, mix, and incubate at room temperature for 30 min in the dark.
8. Add 10 μl of the trypsin solution (final concentration of 5–10 ng/ml), mix, and incubate overnight at 37 °C.
9. Add the iTRAQ™ reagents, which are dissolved separately in 70 μl ethanol, to different samples (e.g., iTRAQ Reagent 114 to sample 1 and iTRAQ Reagent 117 to sample 2), vortex, and incubate at room temperature for 1 h.
10. Combine the contents of each iTRAQ reagent-labeled sample tube into one tube and mix, following with incubation at room temperature for 2 h; quench the reaction with 3 μl glacial acetic acid once the labeling is complete. Combine all labeled samples.
11. Clean up the sample to remove excess iTRAQ reagents, salts, and other interfering compounds. This can be done by batch absorption onto cation exchange chromatography resins, reverse-phase resins, or acetone precipitation.
12. Dry the sample on a Speedvac.
13. Dissolve samples in LC-MS buffer A and transfer to injection vials for MS/MS analysis.
14. Analyze MS data using, for example, Proteome Discoverer with MMTS-labeled cysteines and iTRAQ-labeled N-termini as fixed modifications, and phosphorylation of serine, threonine, and tyrosine and iTRAQ labeling of threonine and lysine residues as variable modifications for the search parameter settings. Alternatively, many iTRAQ analysis tools are freely available, such as LTQ-iQuant [86], IsobariQ [87], OCAP [88], MilQuant [89], PeakQuant [90].

9.2.5.3 SILAC

SILAC is based on the comparison of tagged and untagged peptides by MS using a metabolic labeling strategy. This is achieved by growing cells in an environment where essential components, such as amino acids, are supplemented in either heavy or light isotopic forms. There are several methods of this type of *in vivo* labeling, and selection criteria include the extent of labeling required. One traditional way is to grow cells in an environment where the only nitrogen source is ^{15}N-labeled ammonium persulfate [91], resulting in uniformly labeled amino acids containing heavy nitrogen (^{15}N) only.

A further development and adaptation for mammalian cell cultures is the method for stable isotope labeling by amino acids in cell culture (SILAC), which is nowadays the most common approach for *in vivo* isotopic labeling [92]. This is performed by growing cells in a culture medium that contains $^{13}C_6$-lysine and/or $^{13}C_6$-arginine. These two amino acids are selected since trypsin, the main enzyme used in proteomics to generate proteolytic peptides for MS analysis, cleaves at the C-terminus of lysine and arginine residues. Therefore, all tryptic peptides from cultures grown in SILAC media, with the exception of the extreme C-terminal peptides, contain at least one labeled amino acid.

The key aspect is that, since heavy and light samples are combined prior to sample preparation for MS analysis, the influence of processing errors is minimized, resulting in a much more robust quantitation analysis. This makes this method particularly useful in the detection of small changes in protein levels or PTMs between two to three sets of conditions. Another benefit is that metabolic labeling strategies can yield more than 90% isotopic incorporation in immortalized cell lines [93], again resulting in an improved quantitation result.

The downside of metabolic labeling is that it is not generally compatible with any cell line, as it depends on a cell culture cycle that lasts several days, and the conditions used to incorporate the isotopic tags might also influence the cells directly [10]. Additionally, because of the limited number of heavy isotopes incorporated into lysine and arginine—namely, unlabeled, $^{13}C_6$-, and $^{13}C_6$ $^{15}N_4$-labeled amino acids—in any SILAC experiment, a maximum of three conditions can be studied simultaneously. The following is an adaptation of a previously published protocol [84].

1. Prepare SILAC media. For example, add normal methionine to both "light" and "heavy" medium if SILAC labeling with arginine and lysine only, and add appropriate amounts of "light" and "heavy" arginine and lysine to the "light" and "heavy" media, respectively.
2. Grow cells in "light" or "heavy" SILAC medium according to standard cell culture conditions.
3. Lyse cells by adding 300 µl of a solution containing 6 M urea and 2 M thiourea to a cell pellet or a cell culture dish; then vortex and pellet the debris by centrifuging for 10 min at 16,000–20,000 × g at 18 °C.
4. Collect the supernatant in a new tube, avoiding DNA and the cell pellet.
5. Measure the protein concentration using a standard protein assay and use about 25–50 µg of protein for the in-solution digest.
6. Reduce disulfide bonds by adding DTT to a final concentration of 1 mM and incubate at 37 °C for 30 min.
7. Alkylate cysteins by adding iodoacetamide to a final concentration of 5 mM, mix, and incubate in the dark for 20 min.
8. Quench the reaction by adding DTT to a final concentration of 5 mM.
9. Reduce the final concentration of urea to 3 M by adding an equal volume of 50 mM ammonium bicarbonate.
10. Add endoproteinase Lys-C at an enzyme-to-substrate ratio of 1:100 and incubate at 37 °C for 2 h.
11. Reduce the urea concentration to less than 1.5 M by diluting the lysate with an equal volume of 50 mM ammonium bicarbonate.
12. Add trypsin at an enzyme-to-substrate ratio of 1:50 and incubate at 37 °C for 4 h or overnight.
13. Acidify with trifluoroacetic acid, 1% final concentration, to stop digestion.
14. Analyze the sample by nanoflow LC–MS/MS to identify proteins and peptides.
15. Determine the degree of incorporation by looking for "heavy" and "light" peptides using MS.
16. Analyze MS data using specific SILAC software such as PeakQuant [90], IsoQuant [94], or SILACtor [95].

9.2.5.4 SRM, MRM, and label-free

Selected reaction monitoring (SRM) and multiple reaction monitoring (MRM) are methods of absolute quantitation, also referred to as AQUA. Both are targeted proteomics analyses carried out by spiking complex samples with stable isotope-labeled synthetic peptides that act as internal standards for specific peptides of proteins to be investigated [96]. These labeled peptides are designed to be identical to peptides observed in the samples to be investigated—for example, tryptic peptides generated by sample digestion—so that they co-elute with the target peptide and are simultaneously analyzed by MS/MS. Predetermined calibration curves of the heavy peptides are then used to calculate the concentration of the target peptides to a high accuracy. However, this means that for each target peptide in the sample, a calibration curve has to be generated. The drawback of these techniques is that they are considerably labor-intensive and can also be economically unfavorable.

Rapid and low-cost alternatives compared to other quantitative proteomic approaches have been developed over the last years. These label-free methods are usable for both relative and absolute quantitation and are ideal for large-scale sample analyses in clinical screening or biomarker discovery experiments [97]. The main issue is that they are less reliable to measure small changes and can have a limited range of linear quantitation [98]. However, improved MS instruments and workflows are slowly filling this gap. Protein quantitation is done using either spectral counting or ion peak intensity [99].

Only LC-MS scans are used for relative quantitation by ion peak intensity. The signal intensities of all m/z peaks across all scans are used to determine relative quantities, since these values have been shown to correlate highly with ion concentrations [100]. Because of the considerable amount of data collected from such experimental runs, sensitive computer algorithms are needed for automated ion peak alignment and comparison.

Label-free relative quantitation by spectral counting compares the sum of MS/MS spectra of a peptide across multiple samples; it has been shown to correlate directly with protein abundance [100]. Unlike peak intensity quantitation, special algorithms or other tools are not required for spectral counting, but significant normalization is necessary [101].

Apart from relative quantitation, label-free methods can also be used to determine the absolute concentration of proteins in a sample. The exponentially modified protein abundance index (emPAI), which estimates protein abundance based on the number of detected peptides and the number of theoretically observed tryptic peptides for each protein, determines the approximate absolute protein abundance in large-scale MS experiments [97]. Another method, absolute protein expression (APEX), is based on spectral counts and uses correction factors to adjust protein abundance proportional to the number of peptides observed [102].

Generation of an SRM method

SRM studies are by default hypothesis-driven and focus on a specific set of proteins that correspond to a specific clinical or biological question, such as a biomarker, a biochemical pathway, or a protein network [103].

The critical part of the experimental design is the selection of peptides that will act as surrogates for the proteins of interest. In order to accomplish this, two to three peptides are first selected to perform the quantitation for each protein of interest. These peptides should conform to the expected peptides to be analyzed—for example, proteotypic if the samples were proteolytically processed—and they should be unique to the protein of interest. For previously analyzed proteins in proteomic discovery experiments, the unique peptides observed represent the starting point of the targeted SRM method design. They can be directly imported in specific software packages for SRM method design [104]. Existing MS/MS spectral libraries are queried to extract fragment ions to generate the SRM transitions, usually the most intense assigned fragment ions. If the proteins have not been reported before, the peptide selection is performed in silico using the protein sequences.

The peptides should ionize well in ESI mode and produce doubly or triply charged ions in the mass range of 400–1500 m/z, corresponding in length to peptides of 8–20 amino acid residues. For reasons of practicality, peptides containing residues such as methionine, which can undergo easy modification, are excluded.

Precursor and fragment ion m/z are calculated for each peptide, and the reverse-phase elution time is predicted using hydrophobicity indexes [105]. For each peptide, a series of transitions are defined. If the MS/MS spectra of the peptides are available, five to eight of the most intense y ions are chosen from the reference spectrum. If no MS/MS information is available, the m/z values of the fragments are calculated, and y fragments with m/z values above the precursor ion are selected.

The collision energy in a preliminary study is calculated for each peptide based on the generic formula of collision energy in volts $= 2 + 0.034 \times$ precursor ion m/z. This transition list is exported and uploaded into the instrument method.

The samples are spiked with various concentrations of the selected peptides, and the mixes are analyzed by targeted LC-MS/MS. The SRM transitions are monitored for endogenous and standard peptides.

Design of MRM Transitions/MRM Assays

Generally, MRM analyses can be carried out on any triple quadrupole MS instrument. However, the specific details of parameter optimization and MRM assay setup can differ between instruments [106]. Numerous software solutions exist for both design and analysis of MRM assays [107]. The following protocol can be used.

1. Obtain standard peptides relating to the proteins to be analyzed and dilute each one with 40% (v/v) acetonitrile, 0.1% (v/v) FA, to a final concentration of 200 fmol/μl.
2. Analyze each standard peptide by nanoSpray direct-infusion MS (ESI) to generate MRM transitions.
3. Measure the peptides by enhanced-resolution single MS and enhanced product ion MS/MS scans to obtain molecular weight and fragmentation patterns.
4. Select the monoisotopic m/z of the doubly or triply charged precursor as the reference mass, and choose the three or four most abundant fragments with an m/z higher than that of the precursor.
5. Optimize the parameters that show the highest signal intensity by adjusting the declustering potential, the entrance potential, the collision energy, and the collision cell exit potential.
6. Using the expected mass differential from the standard peptides, calculate the MRM transitions for the corresponding endogenous peptides from the samples to be analyzed.
7. Check for interfering signals by analyzing the standard peptides and the endogenous peptides separately.
8. Dilute the standard peptides to a concentration of 2.5 pmol/μl with 2% (v/v) acetonitrile, 0.5% (v/v) formic acid, and prepare a peptide mixture containing all standard peptides at 100 fmol/μl each in the same buffer.
9. Mix the proteolyzed sample with standard peptides at the desired concentrations; use combinations of different concentrations for both standard peptides and samples.
10. Analyze the sample containing endogenous and standard peptides by targeted LC-MS/MS; monitor the MRM transitions for endogenous and standard peptides.

Label-Free Using Ion Intensities

The number of ions in a peak from a mass spectrum, at a particular m/z ratio, is reflected by the height or area of that m/z detected by the mass spectrometer at any given time.

This is generally known as the ion abundance. The ion abundance cannot be used directly to infer absolute protein or peptide quantities, since each peptide has different ionization efficiencies. However, by comparing the ratio of ion abundances between identical peptides obtained in different experimental runs, it is possible to estimate a differential expression [99]. Here is the protocol.

1. Search all acquired spectra using a database search algorithm to identify all proteins/peptides.
2. Extract the ion abundances for all charge states for each identified peptide and, where necessary, combine them for each unique peptide from each sample and calculate an abundance ratio across all samples.
3. Calculate protein abundance ratios by combining all peptide ratios.
4. Normalize the protein abundance ratios by calculating the mean of all protein ratios, and divide all ratios by this value.
5. Determine the statistical significance of all protein abundance ratios across all samples, including the correlation and covariance values.

Label-Free Using Spectral Counting

A protein's spectral count refers to the total number of MS/MS spectra acquired from proteolytic peptide ions for that specific protein during a LC-MS/MS run. This analysis method is based on the abundance of a peptide, so the more abundant the peptide, the more likely it will be selected for MS/MS analysis. In several comparison studies, it was shown that the correlation of protein abundance with spectral count is better than that which can be obtained from protein sequence coverage or peptide count [100].

1. Search all acquired spectra using a database search algorithm to identify all proteins.
2. For each protein, count all MS/MS spectra for each peptide belonging to the same protein.
3. Normalize the total spectral count across all samples. The total spectral count should be the same under identical data acquisition conditions. Any one sample can be used as the reference value.
4. Determine the statistical significance of protein spectral counts across all samples. A number of different statistical tests such as t-test or Mann-Whitney can be used.

9.3 DATA ANALYSIS

State of the art high-throughput MS-based proteomics methodologies require a considerable amount of data processing, management, and visualization. These are central and critical components (Figure 9.3), and are often some of the most time-consuming steps [108].

The development of better MS machines, technology, and strategies has led to a wider use of proteomics and to a tremendous increase in the development of new software tools, including freely available and open-source programs and scripts, ranging from database search analysis to post-processing of mass spectra and resulting data. Table 9.3 is an overview of selected software libraries, both commercial and open-source, and information on some of the available applications.

9.3.1 Downstream Processing

9.3.1.1 Normalization

Technical and biological variations can lead to deviations in quantified MS peak intensities, resulting in unreliable run-to-run reproducibilities. Therefore, normalization of peak intensities across an MS proteomics dataset is a fundamental step in processing MS data [124]. Furthermore, it is crucial to select the appropriate normalization method, which will have a considerable impact on the downstream analysis. Normalization procedures are generally included and sometimes automatically applied in the software used to process the raw MS data. They must be recalculated for each independent dataset and be independent from the biological factors associated with the experiment.

9.3.1.2 Statistical Analysis

Discovery of biomarkers and establishing biomarker models usually require a statistical analysis of peak patterns, as does feature selection to decide if proteins are promising leads for biomarker candidate selection [125]. The classification rules use information about the contribution to the classification of each variable (e.g., peak intensity) which can then lead to the mathematical identification of biomarkers. Two methods that determine the interesting variables directly are the classification tree [126], which classifies samples based on their values for a small number of proteins, and nearest shrunken centroid (NSC), a progressive sampling algorithm [127]. Linear support vector machines (SVM) use relevant information about variables and features in the form of weights and regression coefficients. This type of analysis is used in many applications to select relevant sets of biomolecules.

Rank products were initially designed for gene selection using gene expression differences between two groups directly [128], but they have also been employed for selection of proteins using a principal component discriminant analysis classification rule [129]. Another classification method is PLSDA, a multivariate inverse least squares discrimination method used to classify features; thresholding of regression coefficients using PLSDA was used to identify potential metabolite biomarkers [130]. A variant of PLSDA is variable importance in the projection (VIP).

FIGURE 9.3 **Data analysis workflow.** Proteomics data processing often requires several steps and more than one software tool; the most common procedures are indicated according to the aim of the analysis.

The VIP value of a variable reflects its importance in the model with respect to the response vector as well as to the projected data [131].

Variable selection using multiple classification rules is computationally more demanding because of the amount of information that has to be permuted. The random forest algorithm, or decision tree analysis, which is typically used in SELDI-TOF-MS biomarker model building, estimates the importance of a given variable by mathematically rearranging its measurements, leaving the rest of the data intact and classifying new samples [132]. Significance tests, such as t-tests and Wilcoxon-Mann-Whitney tests, can also be used to select disease markers, without running a classification algorithm [133].

9.3.1.3 *Identification*

Nowadays, there are a considerable number of diverse mass spectrometers used to generate MS data in proteomics. This is also the case for algorithms employed in querying and cross-comparing tandem MS data [134]. The most popular software packages used in protein identification from raw MS scans are Sequest, MASCOT, OMSSA, and X!Tandem [135]. However, further developments and the emergence of new tools such as Morpheus [136], as well as specialized tools like MaxQuant [137], which is often used for iTRAQ quantitation, will accelerate identification and enhance feature extraction.

9.3.2 Biomarker Pattern Analysis

A diagnostic-proteomics approach does not necessarily rely on the identification of peaks to be useful in diagnosing a disease condition; on the other hand, a biomarker-discovery approach usually does. If, however, these peaks of interest, which show a difference in abundance according to disease states, are subsequently identified and, for example, validated by independent techniques such as Western blotting, it is possible to learn more about biological context and potential impact on a biological system. This diagnostic-proteomics approach has become popularly known as proteomic-pattern analysis [138]. Pattern matching was used

TABLE 9.3 Analysis Tools

Software	Area	Usage	Source	Availability	Reference
Univariate statistics	Statistics	Statistical tools to calculate covariances, confidence values, etc.; well established and easily interpretable; does not work with multiple variables	—	Many software packages available	[109]
PCA	Statistics	Principal component analysis to calculate and visualize potential correlations of datasets; good visual presentation	—	Many software packages available	[110]
Random forest/ decision tree/ support vector machine	Statistics	Classification and regression analysis to build decision models (biomarker models/patterns); random forest controls overfitting through subset selections; number of incorrect predictions increases with decision tree complexity; support vector machine shows poor classification of blinded data with high numbers of variables and dimensions because of overfitting	—	Many software packages available	[111]

successfully in comparing a biomarker profiling study with lists of proteins identified in the same samples, followed by cross-matching of observed proteins and expected peaks using a specific pattern-matching algorithm [139]. Other pattern-matching approaches are used in 2D-gel analysis [140] and LC-MS screens using MassUntangler software [141].

9.3.3 Data Integration and OMICS Analysis

Systems biology, or integrative biology, uses descriptive terms to understand complex interactions based on the analysis of network behavior and dynamic aspects. It combines proteomics, metabolomics, and transcriptomics/genomics data with a systems approach to investigate a clinically relevant complex pathophysiology [142]. Thus, it identifies key signaling cascades [143], inferred metabolic alterations [144], and molecules modulated in highly complex diseases [145]. Apart from the pure gain of knowledge, such holistic multi-OMICS approaches have become increasingly important in healthcare, as they are considered key technologies for personalized and preventive medicine [146]. The addition of chronological and spatial aspects enables mathematical modeling [147]—for example, in signaling or gene activation cascades. This can lead to novel insights into the mechanisms of pathogenesis and can support the development of new therapeutics [148]. Multi-OMICS approaches can also be used to discover novel biomarkers for disease diagnostics [149].

In practical terms, systems biology is currently one of the more demanding scientific disciplines because of its lack of all-encompassing software tools, disparate data sources, data structures, and formats, demanding data processing and interpretation of results as well as skills to judge experimental findings in light of existing knowledge obtained from the scientific community [150].

9.4 DISCOVERY AND VALIDATION

Proteomics has been enthusiastically taken up by the scientific community in all areas of life sciences, and there is an ever-increasing number of studies using proteomic workflows, taking advantage of improved instrumentation, methodologies, and analysis software [168]. Table 9.4 lists a representative number of investigations using the methods mentioned in this chapter to define new and usable biomarkers that might be of clinical benefit in the future.

Additionally, because the level of biological information is also on the increase, the option of looking not just at a specific set of molecules, but rather at the entire biological system, becomes a workable reality. This approach, termed systems biology analysis, is ideally suited to investigating and describing whole-systems perturbations based on disease conditions; it has been applied to several disease models to date, of which a selection is listed in Table 9.5. The following paragraphs focus on diseases and biological systems using proteomic techniques that have garnered particular interest.

9.4.1 Cancer Markers

Undoubtedly, one of the major areas of biomarker investigation using proteomics techniques is cancer research. Numerous studies have been carried out; however, the usability of results as biomarker-screening tools in the clinical setting is relatively low. To a lesser extent, the use of MS for discovery of proteomic biomarkers as a cancer diagnostic tool, using various analytical platforms, has been reported [139].

One of the main applications of MS-based analyses is screening and detection of cancer in its early stages, as well as prediction of cancer development [176]. Urine as a source of screening medium has gained considerable interest because of its noninvasiveness and biomolecular stability compared to serum. Proteomic urinary biomarker screening of bladder cancer samples has shown several proteins to be differentially present—namely, bikunin and pro-urolinase-plasminogen activator [177], apolipoprotein A-I, apolipoprotein A-II, heparin cofactor 2 precursor, and peroxiredoxin-2 [178], or PLK2 [179]. In contrast, ovarian cancer biomarkers have been described as fragments of fibrinogen alpha, collagen alpha-1, and fibrinogen beta-NT [180].

Metzger et al. [181] used CE-MS to establish a biomarker model based on 42 urinary peptides for the diagnosis of cholangiocarcinoma with a sensitivity of 83% and a specificity of 79%. The majority of peptides identified in this study were fragments of interstitial collagens; immunostaining of liver sections for matrix metallopeptidase 1 showed an increased expression of interstitial collagenase in liver epithelial cells of cholangiocarcinoma patients. This presented a possible explanation for the observed altered collagen fragmentation. SELDI-TOF-MS was also used extensively in the discovery of cancer biomarkers.

A study by Husi et al. [139] used a combination of SELDI-TOF-MS, LC-MS/MS, and pattern matching to identify a urinary biomarker profile of six peptides in upper gastrointestinal cancer with a sensitivity of 96% and a specificity of 72%. The identified molecules consisted of S100-A6, S100-P, S100-A9, S100-A12, ITIH4, and ubiquitin. Several of these were validated by Western blotting.

9.4.2 Cardiovascular Diseases

Stroke and heart failure rates are globally on the increase; these severe diseases are associated with both poor prognosis and adverse outcomes [182]. Several studies have sought to uncover the molecular pathways involved using various heart failure models and proteomic techniques, including

TABLE 9.4 Proteomics in Biomarker Research

Disease Area	Disease	Tissue	Platform	Identified Biomarker	Number of Modulated Proteins/ Models/Peak Patterns	Reference
Fibrosis	Cystic fibrosis	Nasal cells	2DE, MALDI	—	65 biomarkers	[151]
Cancer	Esophageal carcinoma	Laser capture of microdissected tissue	2D DIGE, MALDI	Annexin I, gp96	165 biomarkers	[152]
Cancer	Hepatocellular carcinoma (HCC)	Serum	2DE, LC-MS/MS	Complement C3, APOA1		[153]

TABLE 9.5 Continued

Disease Area	Disease Model	Tissue	Platform	Target Identification	Modulated Proteins/ Models	Pathways	Reference
Cardiovascular	Chronic kidney disease (CKD), type 2 diabetes mellitus (T2DM)	Serum	iTRAQ, MRM	—	—	Lipid and small molecule metabolism, pathways that lead to disruption of glucose homeostasis and blood coagulation	[172]
Cardiovascular	Calcific aortic valves	Tissue	iTRAQ	Tenascin-X	105 differentially expressed proteins	Blood coagulation, integrin signaling pathways, collagen fibrillogenesis	[173]
Neurological	Schizophrenia	Serum	LC-MS/MS	—	27 differentially expressed proteins	Complement and coagulation cascades, nervous system development and function, humoral immune response, inflammatory response, immune system	[174]
Neurological	Parkinson's disease (PD)	Serum	iTRAQ	Complement component 4B, apolipoprotein A-I, α-2-antiplasmin, coagulation factor V, serotransferrin, clusterin	26 differentially expressed proteins	Oxidative stress, mitochondrial dysfunction, abnormal protein aggregation, lipid metabolism, inflammation	[175]

LC-MS/MS coupled iTRAQ [183], MALDI-MS/MS in conjunction with DIGE [184], and so forth. This research has led to a commonly accepted pathway model involving glycolysis, fatty acid metabolism, and elements of the TCA and mitochondrial electron transport machinery [185]. However, proteomic heart failure biomarkers that can be used in a clinical setting remain elusive.

A recent publication by Scott et al. [186] identified six potential serum biomarkers using SELDI-TOF-MS, but none of the proposed markers were predictive for suitability of patients for clinical intervention therapy. A study by Kuznetsova et al. [187] used CE-MS to investigate urinary biomarkers in hypertension. They showed a peak pattern of 85 discriminatory peaks and, after adjustment for multiple testing, three potential biomarkers remained sufficiently different to distinguish healthy controls from patients having essential hypertension with left ventricular diastolic dysfunction. Despite these promising initial results, clinical applicability remains to be shown, since neither molecular identification of the proposed biomarkers nor consequential validation by independent techniques has been demonstrated.

9.4.3 Kidney Diseases

Glomerulonephritis is one of the major causes of renal failure and an important factor in morbidity and mortality in multifaceted kidney diseases [188]. Glomerular disease diagnosis involves assessment of renal function, quantification of proteinuria, and urine analysis by dipstick testing and microscopy. These results are useful in determining renal injury, but they are poor indicators of pre-existing or co-occurring inflammatory conditions. This drawback has led to the study of a number of estimated biomarkers, including cytokines, chemokines, and growth factors, proposed to be involved in glomerular disease. Recently, MS has been used to screen for urine biomarkers in glomerulonephritis, both in animal models and in patients at various disease stages [189]. Using SELDI-TOF-MS, Mosely et al. [190] described two urinary biomarkers with 92% sensitivity and 92% specificity that discriminate active from inactive lupus nephritis and allow detection of relapse and remission earlier than traditional clinical markers.

Similarly, via CE-MS and 2D-gel approaches, a number of urine biomarkers identified in immunoglobulin A nephropathy were put forward to discriminate between glomerulonephritis and other proteinuric glomerular diseases [191]. Interestingly, Haubitz et al. [192] observed changes in the excretion of peptide peak patterns with increasing use of an antihypertensive drug, which opens up the possibility that the observed urinary biomarkers can be used in the future to monitor the effectiveness of clinical drug treatment in glomerulonephritis. This is furthermore supported by an independent study by Rossing et al. [193], in which it was found that treatment of diabetic nephropathy patients with the angiotensin II receptor blocker candesartan significantly reduced the excretion of disease-specific biomarkers toward levels seen in healthy control urine.

Another important cause of morbidity and mortality in patients with both type 1 and type 2 diabetes mellitus is diabetic nephropathy. Microalbuminuria is an important early-onset marker of this condition, but by the time it becomes apparent, significant glomerular injury has already occurred. MS was used in a number of studies to identify urinary polypeptide patterns in patients with normoalbuminuria and less robust patterns of microalbuminuria in diabetes [193]. This suggests that it might be possible to establish a predictive model to identify patients at risk of renal injury before nephropathy becomes established.

9.4.4 Preeclampsia

Preeclampsia is the major leading cause of maternal and neonatal morbidity and mortality, accounting for 5–7% of all pregnancy-associated complications worldwide. This is a multifactorial disease that is characterized by co-occurring hypertension and proteinuria [194]. Several studies have been undertaken to understand the molecular causes that can lead to preeclampsia and understand its pathogenicity, as well as to identify potential preeclampsia biomarkers. In particular, the study undertaken by Carthy et al. [195] demonstrated with good confidence a predictive urinary biomarker panel of 50 peptides at week 28 of pregnancy prior to onset of the disease. However, it was not possible to effectively predict preeclampsia before the 28th week of pregnancy. Potential biomarkers were identified as fibrinogen α chain, collagen α chain, and uromodulin fragments.

9.4.5 Neurological Complexes

One of the most complex human biological systems, and the least well understood, is undoubtedly the brain and its peripheral pathways. A major breakthrough in 2000 by Husi et al. [196] was the discovery of a vast, tight molecular network of synaptic proteins incorporating at least 250 proteins into a substructure of post-synaptic density. Many of the proteins were known to be key players in learning and memory; however, the demonstration of a direct association and preassembly of pathways and signaling machineries to such an extent had never before been shown, neither in the context of neuroscience nor in any other system [197]. This led to the speculation that complex diseases such as Alzheimer's or Parkinson's were a result of network perturbances, where unrelated damages in genes/proteins result in the same outcome [198].

Protein biomarker discovery from serum and other biological fluids using MS-based methodologies and associated technologies for the identification of protein biomarker signatures has been applied to neuropsychiatric disorders [199] such as schizophrenia [200], neurodegenerative conditions like multiple sclerosis [201], Alzheimer's [202], Parkinson's [203], and neurodevelopmental diseases such as attention deficit hyperactivity disorder [204] and autism spectrum disorder [205]. Although the latter two conditions are less well described in proteomic pattern profiling, they are found to be associated with metabolic pattern shifts such as serotonin levels. However, on the proteomics level it can be demonstrated that latrophilin LPHN3 expression levels are strongly associated with attention deficit hyperactivity disorder [206].

In particular, a number of MS-based methods have been used to identify potential biomarkers for multiple sclerosis. Stoop et al. [207] utilized peptide and protein profiling for detection and characterization of differences between controls and multiple sclerosis patients. In a follow-up study, they used MALDI-MS for semiquantitative analysis of differentially abundant proteins [208]. A study published by Comabella et al. [209] used iTRAQ analysis of cerebrospinal fluid from multiple sclerosis patients. They found 23 proteins that were differentially expressed in individuals with worsening multiple sclerosis conditions and those remaining stable. One of the proteins differentially expressed, chitinase-3-like 1, was further validated independently with ELISA. Another study using cerebrospinal fluid from multiple sclerosis patients was reported by Mattsson et al. [210]. The researchers demonstrated a robustly altered pattern of 24 proteins, with a down-regulation of chromogranin B and secretogranin II in multiple sclerosis.

Alzheimer's disease has been the focus of a substantial number of proteomic and diagnostic biomolecule studies. For example, Korolainen et al. [211] listed 26 proteins whose expression pattern is statistically altered in this disease, and Zetterberg [212] presented 30 proteins in cerebrospinal fluid as potential Alzheimer's biomarkers. A recent study by Choi et al. [213] used an MRM-based analysis of cerebrospinal fluid samples in validation of Alzheimer's disease diagnostics. MRM quantification demonstrated a high correlation with ELISA analysis of Alzheimer's-associated biomarkers, including Aβ1-40, Aβ1-42, retinol-binding protein, and cystatin C.

Other proteomic studies used SELDI-TOF-MS to define an Alzheimer's biomarker pattern. For example, Simonsen et al. [214] generated a biomarker profile of 5 biomolecules in cerebrospinal fluid with 100% sensitivity and 97% specificity. Other approaches include Yin et al.'s combination of 1D-PAGE and 2D-PAGE with LC-MS/MS, which detected 21 proteins that showed a different abundance between this disease and controls [215]. Finehout et al. [216] used 2D-PAGE to observe 23 differences in protein expression patterns. Hu et al. [217] used 2D-DIGE to observe differences between patients with mild dementia and no cognitive disease. Finally, Abdi et al. [218] used iTRAQ to identify more than 1500 proteins and demonstrate that the expression pattern of 136 molecules is uniquely changed in cerebrospinal fluid from Alzheimer's patients compared to Parkinson's disease sufferers, patients with dementia with Lewy body and controls, and 73 proteins with a modulated expression uniquely found in Parkinson's disease patients.

A number of proteomic studies have been conducted to discover novel biomarkers for Parkinson's disease, using techniques such as iTRAQ or 2D-PAGE. One example is the DIGE approach by Maarouf et al. [219]. A recent study by Lehnert et al. [164] employed iTRAQ and MRM to demonstrate 16 candidates as discriminators of Parkinson's disease in cerebrospinal fluid, including tyrosine-kinase-non-receptor-type 13, netrin-G1, golgin-160, and apolipoprotein B-100. Pan et al. [220] used SCX in combination with LC-MS/MS and SILAC to absolute quantify five proteins associated with this disease.

9.5 PERSONALIZED MEDICINE

Tailored medical care has been fueled by the development of modern sensitive technologies to comprehensively monitor and assess DNA, RNA, protein, and metabolite data in patients. Some validated and approved molecular tests are already used in therapeutic decision making [221,222]. However, a number of methodologies require further improvements in cost-effectiveness and robustness, as well as in general applicability and response to regulatory hurdles, prior to fulfilling the promise of personalized molecular medicine. An initial problem is the ability to handle and manage the tremendous amount of data generated by high-throughput methodologies to allow further visualization and downstream data analysis, as well as data integration of multi-OMICS approaches. Additionally, computational tools that allow such multidimensional data analysis and knowledge building and extension are somewhat sparse, but they are necessary in achieving improved patient outcomes.

Systems biology, which integrates a variety of scientific disciplines with biological and medical background information, is an iterative process for describing and visualizing interconnected events within cells, tissues, and whole systems. It describes how various molecular shifts contribute to further modulated events in terms of environmental and network connectivity impacts (e.g., gene pattern shifts, modulated signaling cascades, and runaway or inhibited metabolic pathways) and ultimately altered cell behavior under disease conditions. Such a cross-disciplinary effort is necessary to understand and convert multidimensional datasets into useful information that can classify and stratify disease states and identify potential specific novel biomarkers which can be used in prognosis, diagnosis, and response to therapeutic agents. An in-depth understanding of modulated events, using targeted therapeutics on many biological and pharmacological levels, is an absolute requirement for preventing adverse outcomes and accidental side reactions, as well as for avoiding ineffective treatments on a personalized level.

The systems biology-led discovery of key elements in aberrant pathways, molecular drivers, and biomarkers has the potential to lead to novel regimes in clinical trial design, targeting subpopulations of disease cases where a clear benefit of a targeted approach has yet to be identified, and it might increase the success rate and accelerate the implementation of effective treatments in the clinical setting.

9.6 CONCLUSIONS

Pharmacogenomics, biomarker discovery, and proteomics play an important role in disease characterization and therein, therapy-appropriate samples for molecular research are extremely important.

There are several proteomic workflows available that allow for many combinations and alternatives. The main factors dictating the most appropriate proteomic workflow are the objective of the study and the type of samples available.

In proteomics, sample preparation methods are mainly aimed at reducing the complexity of biological systems and rendering samples compatible with MS analysis. MS scans provide a rich source of information containing peak patterns, distribution, and quantitation, and tandem MS/MS scans can be used to mathematically reconstruct a probable amino acid sequence using appropriate databases. Important downstream processing steps include data processing, management and visualization of results, steps that are normally achieved using more than one software tool. Although some validated and approved molecular tests are already used in therapeutic decision making, advancements in personalized molecular medicine will depend on further improvements in the cost-effectiveness and applicability of a number of technologies, the response from regulatory agencies, and the ability to handle and manage the tremendous amount of data generated by high-throughput methodologies.

ACRONYMS

2D-PAGE	2D polyacrylamide electrophoresis
APEX	absolute protein expression
CE	capillary electrophoresis
CHCA	α-cyano-4-hydroxycinnamic acid
CID	collision induced dissociation
DIGE	difference gel electrophoresis
DMF	N,N-dimethyl formamide
ECD	electron capture dissociation
emPAI	exponentially modified protein abundance index
ESI	electrospray ionization
EST	expressed sequence tag
ETD	electron transfer dissociation
FASP	filter-aided sample preparation
GO	gene ontology
HCD	high-energy collision-induced dissociation
ICAT	isotope-coded affinity tag
IEF	isoelectric focusing
IPA	ingenuity pathway analysis
LC	liquid chromatography
MALDI	matrix-assisted laser desorption-ionization
MARS	Multiple Affinity Removal System
MELDI	material-enhanced laser desorption/ionization
MiMI	Michigan Molecular Interactions
MRM	multiple reaction monitoring
MS	mass spectrometry
MudPIT	multidimensional protein identification technology
NSC	nearest shrunken centroid
PAGE	polyacrylamide gel electrophoresis
PCA	principal component analysis
pI	isoelectric point
PTM	post-translational modification
SELDI	surface-enhanced laser desorption-ionization
SILAC	stable isotope labeling by amino acids in cell culture
SPA	sinapinic acid
SRM	selected reaction monitoring
SVM	support vector machine
TOF-MS	time-of-flight mass spectrometry
TOF	time-of-flight
VIP	variable importance in the projection

10.1 OVERVIEW

The publication of the draft human genome on February 15, 2001, [1] was a significant milestone in the understanding of human disease and diagnosis. An enormous repository of information on the basic building blocks of the human organism had been made available to researchers, allowing groundbreaking research into the relationship between genes and inherited diseases and disease susceptibility. However, by exploring the linkage between genetic influence and the overall phenotype, it was demonstrated that sequencing the genome is a starting point in the analysis of the complexity of an organism.

Genetic events propagate from DNA (the genotype) through transcription and translation to ribonucleic acids and proteins [2]; these in turn have an effect on the small molecules that make up the bulk of a cell. The combination of these levels creates the phenotype [3]. Crucially, extracellular and extraorganismal signals propagate via small molecules, proteins, and nucleic acids, effecting transcription, translation, post-translational protein modification and chemical reactions with other small molecules.

The discipline of genomics was formed to exploit the plethora of genetic information available both on human disease, including single-nucleotide polymorphisms and epigenetic modifications within the human genome, and from genomic data from other human health–related organisms such as pathogens. It has already had significant impact on health research, via genome-wide association studies [4–6] and SNP analysis [7–9].

Following on from these efforts, post-genomic technologies have developed to exploit the enormous quantity of information available at the protein and metabolite levels, known as proteomics and metabolomics, respectively.

10.1.1 The Metabolome and Metabolomics

The metabolome was first described by Oliver and colleagues in 1998 [10], during their pioneering work on yeast metabolism, as the complete complement of small molecules in a biological system or fluid. It therefore follows that the discipline of metabolomics is the analysis of the metabolome: the small molecules in a biological sample. Metabolomics is also referred to as metabonomics or metabolic profiling by some groups, but *metabolomics* is the term most commonly used and is therefore used here.

Use of gas chromatography–mass spectrometry for metabolite profiling of clinical urine samples is possibly the earliest application of what we would now describe as metabolomics, dating from the 1970s [11–13]. The application of nuclear magnetic resonance spectroscopy to profile clinical samples was pioneered by Nicholson and others in the 1980s [14–16]. Later, mass spectrometry coupled with both liquid chromatography [17] and capillary electrophoresis [18] came to be applied to metabolomics to round out the analytical techniques available.

10.1.2 Biochemistry of the Metabolome

Unlike the genome (comprising only 4 different nucleotides) and the proteome (comprising 20 different amino acids), which have a restricted set of building blocks (excluding epigenetic and post-translational modifications, which tremendously complicate these disciplines), metabolites, as individual molecules, include an enormous diversity of organic structures and functional groups that allow them to perform their particular functions. Indeed, these building blocks—amino acids, phosphosugars, nucleotides and their precursors, and degradation products—are all metabolites.

While many metabolites possess functions intrinsic to their structures, they do not exist in isolation *in vivo*. Metabolites are the substrates of enzymes and are chemically modified in anabolic and catabolic processes. Substrates may enter cells from the extracellular matrix and be transported out again as secreted molecules. They can also exist in chemical equilibrium with other molecules and convert readily between two states. For ease of reference, a series of chemical reactions mediated by enzymes in a cell are described as pathways. They include the most basic functions of any living cells, including

- Energy generation via glycolysis, the tricarboxylic acid cycle, the pentose phosphate pathway, and fatty acid oxidation, coupled with the electron transport chain; energy storage via gluconeogenesis; and fatty acid synthesis or glycogen synthesis.
- Synthesis of macromolecules via DNA replication, tRNA synthesis, and protein synthesis.

Understanding these pathways is critical to the interpretation of metabolomics data. The reader is encouraged to refer to biochemistry textbooks for help in interpreting the data [19–21].

Pathways themselves do not exist in isolation, but the inputs and outputs of each pathway are themselves the products of other pathways such that all pathways are interconnected in a complex network (see Figure 10.1) that constitutes an organism's complete metabolism [22]. This provides an enormous analytical challenge because, for example, an extremely sensitive method for the detection of organic acids may be unsuitable for the detection of amine compounds. As a consequence, the researcher must either focus her efforts on a single analytical platform

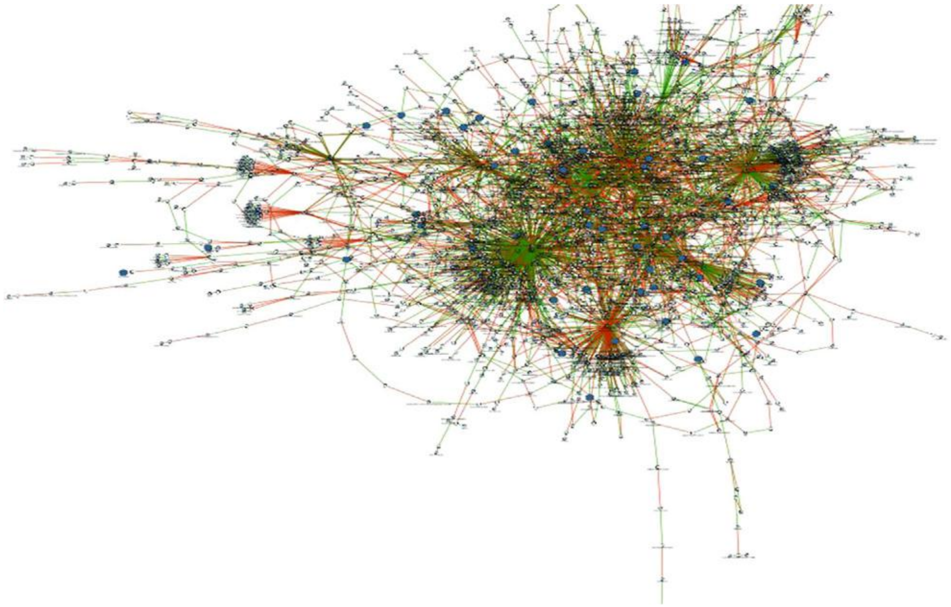

FIGURE 10.1 Complete network of plant metabolites. Metabolites are nodes; enzymatic reactions are edges. Some metabolites, notably water, are excluded from the network due to their ubiquity in reactions. Note the dense clusters surrounding some nodes, which are the consequence of highly promiscuous metabolites such as ATP. *Source: Image generated using MetExplore* [23].

that is capable of detecting a subset of the metabolome, or apply multiple methods to each sample to improve overall coverage.

The total number of metabolites in a biological system is currently the subject of considerable debate, with estimates of between a few hundred for small eukaryotes [24] to thousands in higher mammals [25], to hundreds of thousands in plants [26], with their complex array of secondary metabolites. In addition, while drugs and xenobiotics are generally not considered to be metabolites per se, analytical techniques used to detect endogenous metabolites also detect drugs because of their similar physicochemical properties; therefore, metabolomics is a powerful tool for drug mode-of-action studies.

10.1.3 Applications of Metabolomics in Clinical and Biomedical Research

While analysis of the entire human metabolome, even at the low estimate of a few thousand metabolites, is a goal that metabolomics is far away from reaching, the capability to analyze hundreds of individual small molecules or profile the characteristic signatures of the entire metabolome makes metabolomics an extremely powerful tool that can be applied to a wide variety of biological questions. In cancer science, the Warburg effect [27] of altered energy metabolism in tumor cells has recently been an important target of metabolomic research, with several groundbreaking papers on the energy metabolism of cancer [28,29]. Moderate-scale clinical metabolomics studies in the cardiovascular field, including preeclampsia [30], diabetes [31], and stroke [32], have provided clues as to common disease mechanisms. More specific studies on organs and tissues associated with significant issues in human health have been performed (e.g., liver function [33], pancreatic cancer [34], and lung function [35]).

Parasite (e.g., Barrett et al. [36], Vincent et al. [37], and Vincent et al. [38]) and bacterial (e.g., see references [39–41]) metabolomes that respond to drug action and host interactions have been extensively studied. Indeed, there is a growing interest in the microbiome and metabolomics [42,43] because, while genomics can provide descriptive analyses of the species of microorganisms and their microenvironments (e.g., the gut), the majority of metabolites are cross-species, which allows researchers to study the complete metabolome produced by a community of microbes, including its unique molecules, toxins, and other compounds.

Gas-chromatography mass spectrometry (GC-MS) is particularly powerful in the profiling of samples that contain molecules with structural similarity, such as sugars [44–48], drugs of abuse [49–51], and steroids [52–55]. While the majority of applications are targeted methods for quantitation, GC-MS has also been used for global metabolomics profiling [56–60].

Clinical samples analyzed by nuclear magnetic resonance (NMR) metabolomics include whole blood [61], reconstituted blood spots [62], plasma [63], serum [63], urine [63], saliva [64], cerebrospinal fluid [65], and digested tissue biopsies [63]. NMR-based metabolomics has also been used in lipoprotein analysis for prediction of cardiovascular risk [66,67], early identification of sepsis in critically ill patients [68,69], identification of novel inborn errors of metabolism [70], and drug toxicity [68,71].

Many organisms that model human disease have also been analyzed by metabolomics. For example *Drosophila* studies have been related to kidney function [72–74] and spleen function has been studied in mice [75]. Finally, interdisciplinary projects spanning bioengineering and orthopedic surgery have used metabolomics to optimize surfaces for the maintenance and differentiation of stem cells [76–78].

10.1.4 Experimental Design for Metabolomics

Of course, with such a diversity of applications, good experimental design is essential to achieving high-quality results. It is important to decide whether the experiment will be an unbiased study for hypothesis generation or a specific study chosen to test a hypothesis [79]. The former is the canonical biomarker discovery experiment, while the latter exemplifies validation of biomarkers in a larger cohort.

As in any experiment, a sufficiently large number of controls must be carefully chosen to eliminate bias. For health/disease studies, it is important to use positive and negative controls to separate general effects of ill health from specific disease-associated markers. Samples should also be appropriately randomized and quality control samples must be rigorously acted on if the data obtained fail to meet appropriate standards to eliminate or compensate for inter- and intrabatch variation [80]. Internal standards should also be selected to ensure effective extraction [81].

An appropriate number of biological replicates should be chosen to provide the appropriate statistical power [82]. More specifically, the larger the coefficient of variation in metabolite levels in the samples, the higher the number of replicates and the larger the minimal fold change required for statistical significance. In general, for clinical samples from small sample groups only very large variations from control levels have statistical power. Less than twofold changes in metabolite concentration in highly variable clinical datasets require very large numbers of samples (hundreds or thousands, dependent on the variation observed). While well-controlled cultured cells have low variation, a smaller number of replicates provides similar power. Technical variation in metabolomics experiments is predominantly lower than biological variation [83]. A typical experimental design for a simple pairwise comparison is shown in Figure 10.2.

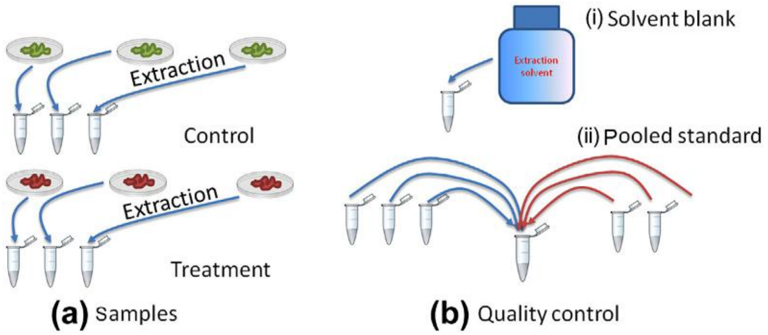

FIGURE 10.2 Simple experimental design of a pairwise metabolomics comparison. (a) Minimum three biological replicates from each state to be analyzed (replicate numbers should be carefully chosen to optimize detection of the desired fold change). An aliquot of extracted fresh medium could be added to these samples, as well as the spent medium from each biological replicate, to observe depletion of metabolites. (b) Quality control samples, including a solvent blank (i) to eliminate spurious compounds introduced in the extraction solvents and (ii) a pooled standard (i.e., a mixture of a small aliquot of the other samples) to enable tracking of compound degradation, batch effects, and instrument drift.

Once the experiment has been carefully planned, it is important to select an analytical method that will have the best chance of producing the desired outcome.

10.2 METABOLOMICS TECHNIQUES AND TECHNOLOGIES

While all "omics" technologies are capable of providing information on the state of an organism, metabolomics can also provide information on food or medium intakes as well as outputs in terms of urine, feces, spent media, and so forth. This application of metabolomics to the inputs and outputs of a system, coupled with analysis of intracellular metabolites, provides additional information. Thus it is possible to determine by comparison between spent and fresh medium that cells have depleted a compound from their environment. A commonly described example of this is the consumption of glucose from the medium. Fresh medium may contain large quantities of glucose; spent medium may not. If there is a very small pool of glucose in the intracellular metabolome, it can be inferred that the glucose has been taken up and fully utilized. Conversely, if glucose is low intracellularly and unchanged between fresh and spent medium, this may indicate that the glucose is not being used by these cells.

Metabolomics uniquely comprises a growing number of competing platforms. The primary tools for metabolomics analysis are liquid or gas chromatography hyphenated to mass spectrometry (LC-MS or GC-MS) and nuclear magnetic resonance (NMR). Capillary electrophoresis, as pioneered by Soga [18], is becoming more popular as a separation method for charged metabolites prior to mass spectral analysis. High-throughput spectroscopic profiling techniques relying on FT-IR [84,85] and Raman spectroscopy [86,87] have also become popular. Each methodology has strengths and weaknesses for particular experimental types, which should be borne in mind when designing a particular type of metabolomics experiment.

In this section, we follow the four major classifications of metabolomics experiment (fingerprinting, metabolite pool analysis, flux analysis, and metabolite profiling) that are dealt with in Birkemeyer et al.'s excellent review on metabolomic experimental paradigms [88].

10.2.1 Fingerprinting

Metabolite fingerprinting is essentially a sample stratification and classification strategy. In this type of experiment, the identification of individual compounds is not the focus, as the principle is to obtain diagnostic patterns from the data that can be used, for example, to distinguish disease status from healthy status. This strategy was pioneered in the NMR, FT-IR, and Raman spectroscopy fields, and it has been applied to several major health issues such as coronary heart disease [66] and diabetes mellitus [89].

10.2.1.1 Metabolite Fingerprinting via NMR Spectral Binning

For metabolome-wide association studies (MWAS), multivariate statistical methods are commonly used [68,90]. High-throughput NMR is performed on the samples. The data are binned and commonly, orthogonal PLS multivariate analysis is performed on the raw spectra, with correction for false discovery rate [68,90]. Once peaks that distinguish cases from controls (or similar) are identified as being important, the unknown metabolite is then identified. This is essential for biological interpretation.

Metabolic fingerprinting can be used to great practical effect—for example, in the iKnife, developed by Balog et al. [91] for real-time tissue identification during tumor surgery.

10.2.2 Metabolite Pool Analysis

The canonical targeted metabolomics experiment is essentially one where the pool of metabolite abundances is assessed (for an early example, see reference [92]). When applied to both LC-MS (e.g., see reference [93]) and GC-MS [94], absolute levels of a particular metabolite can be obtained with the addition of a 13C-, 15N-, or deuterium-labeled internal standard to the sample, accompanied by preparation of a standard curve. This obviously renders the experiment a targeted one, where only the metabolites of interest are obtained. Some efforts to produce uniformly labeled organisms have resulted in a larger number of available labeled standards [95,96], but this requires that the organism in question be culturable in bulk and have identical metabolites to those of interest, and that standard curves for abundance are still prepared for each metabolite.

Metabolite pool analyses are static—they provide no information about rates of change or movement of metabolites. They simply tell you that one or more metabolites change or do not change in abundance as a result of a stress or treatment. For drug mode-of-action studies or analysis of a knockout mutant, if the drug is an enzyme inhibitor, the metabolite prior to the enzyme is likely to be significantly upregulated, and the metabolites downstream will be downregulated or not present post-inhibition. Due to the presence of metabolic shunts that can route around biochemical pathway blockages, this is not an infallible method for analyzing the phenotype of a mutant or drug treatment, but in many cases it can produce valuable data.

Metabolite pool analyses are the standard clinical measures of metabolites. Biomarkers such as glucose for diabetes; bilirubin, used to screen for or monitor disorders of the liver; urea and creatinine used to monitor kidney function; and lactate to detect hypoxia are measured routinely as they provide an indication of dysfunction of biochemical pathways.

10.2.3 Metabolite Profiling by MS

Metabolite profiling is somewhat halfway between observing the overall phenotype by using a metabolomic measure and applying a targeted approach. Metabolite profiling focuses on identification of the largest number of compounds possible, sacrificing absolute quantitation of the sample in exchange for relative quantitation of a far greater number of compounds.

Mass spectrometers are most commonly used for this purpose, as their sensitivity to individual compounds is far greater than any other technique. It is possible to produce relative quantitation between groups of samples, such as wild type/mutant or healthy/diseased for a large number of compounds [80,97–99]. Further details on MS profiling can be found in later sections.

10.2.4 Metabolite Profiling Using NMR

NMR metabolomics can also restrict analysis to a smaller set of well-characterized metabolites. For example, the Ala-Korpela group's method measures over 200 metabolite measures: >100 directly and >100 derived. Directly measured metabolites include >20 amino acids and other clinically relevant metabolites such as glucose, creatinine, and 3-hydroxybutyrate. Also directly quantified by NMR are approximately 80 measures of lipoprotein subclass and lipoprotein content. The 99 derived measures include apollipoproteins, total branched-chain amino acids, Fischer ratio for liver fibrosis, and lipid ratios [100].

It is common in NMR metabolite profiling experiments to apply multiple pulse programs or differential extraction of samples to increase the number and type of compounds detected. The exemplar method uses three different "windows": the LIPO window for lipoproteins and the low-molecular-weight metabolites (LMWM) window, which are both performed on native serum, and the LIPID window, which is performed on extracted lipids [101].

The LIPO window is a standard 1D-^{1}H-NOESY pulse program (to be discussed later). The spectrum obtained contains highly overlapping spectra. The baseline is automatically zeroed and the peaks are aligned. The albumin background must be subtracted [103]. Regression modeling is used to quantify VLDL, LDL, IDL, HDL, and triglycerides. These models are cross-validated to NMR-independent lipid and lipoprotein analysis [101,103].

The LMWM window is a standard CPMG pulse sequence [101]. As described in the Section 10.3.2. Common 1D NMR Pulse Programs, the FIDs are acquired after a longer period, once the larger proteins and lipoproteins have stopped spinning. There is therefore much less spectral overlap. The LIPID window is obtained from extracted lipids reconstituted in deuterated chloroform containing TMS as the internal standard [101]. (See Figure 10.3.)

The results of all the different windows are brought together, and the 99 derived measures are calculated. Self-organizing maps, based on unsupervised pattern recognition of the spectra, are then used to group patients [103]. Other clinical measures are then overlaid on these maps as a visual representation of the correlation between the spectra and the variable of interest; p-values are also calculated [104].

The huge benefit of this method is that it is high-throughput, at almost 200 samples per day, which makes it ideal for large clinical cohorts. It has already been shown to be important for risk assessment for cardiovascular disease [103], prediction of diabetic complications [104], development of cognitive impairment and Alzheimer's disease [105]. Moreover, it has been used to observe the effect of birth weight, diet, physical activity, and timing of puberty on the NMR metabolites detected.

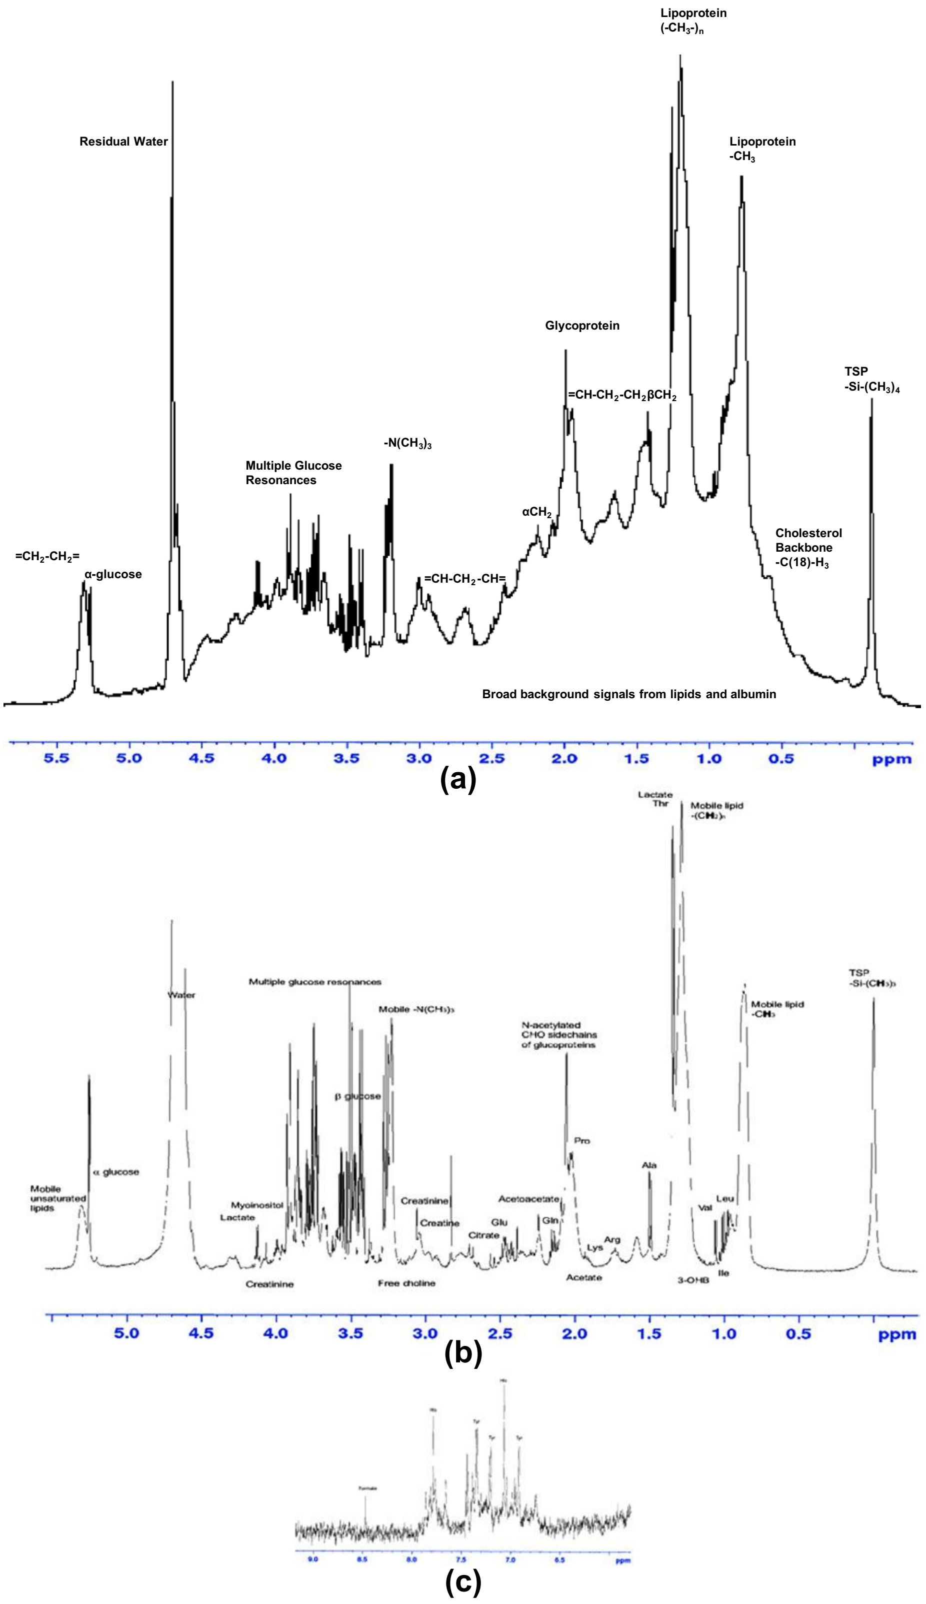

FIGURE 10.3 Example ^{1}H NMR spectra of serum obtained by the Ala-Korpela method. Samples were analyzed on a 14.1 T (600 MHz) NMR with Avance III HD console. (a) ^{1}H NOESY (LIPO window). (b) ^{1}H CPMG (LMWM window). (c) Aromatic region of LMWM window. Note that the large diffuse background in the LIPO window has been suppressed in the LMWM window. The resonances in the LIPO window can be used to determine quantitative lipoprotein profiles. The LMWM window is used to identify and quantify an array of small molecules. The inset shows the aromatic amino acid resonances. *Source: Annotation based on Soininen et al.* [102].

As the method is high-throughput and can identify and quantify multiple metabolites, it combines well with genome-wide association studies [106,107]. The more detailed the phenotyping is, the greater the ability to detect genotype-phenotype associations. This high-throughput NMR method has been used to identify genes associated with heritability of the above metabolites, especially lipids [100]. The method has also been used to identify novel genes associated with atherosclerosis [108].

10.2.5 Flux Analysis

Metabolic flux is the passage of a metabolite through a reaction system over time, and flux analysis is the combination of time-course methodologies in metabolomics and computational modeling of pathways. It is one of the most effective methods for analyzing pathways and determining the fate of a molecular substrate (see reviews in references [109,110]) and is used in fields as diverse as synthetic biology [111], antiviral therapy [112], and cancer [113].

Essentially, in stable isotope labeling an organism is provided with a food, usually medium, although some success in stable isotope labeling in higher organisms has been obtained which contains a heavy labeled version of a particular metabolite. The most common example in metabolomics is the application of ^{13}C glucose to a cell culture to trace the fate [114]. Labeled substrate is normally added in a 50% load with the unlabeled compound. Time courses investigating the rate of incorporation of a labeled substrate can be applied to inform flux balance analysis of a specific biochemical pathway with the use of appropriate software such as MzMatch.ISO [115] or MAVEN [116]. Metabolic flux analysis in the era of metabolomics can be performed using either mass spectrometry or NMR platforms, with characteristic gaps between mass peaks denoting labeled and unlabeled compounds in the case of the former.

^{13}C signals can also be detected by NMR, one of the advantages of which is that the chemical shifts are spread over approximately 200 ppm [71] (see the relevant section). Natural abundance ^{13}C (1.1%) can be difficult to detect due to the low abundance and reduced sensitivity of ^{13}C NMR. ^{13}C labeled metabolites can be made, which can help with the few metabolites that are ^{1}H NMR invisible, such as uric acid. This is a result of either a lack of protons (azide) or a very rapid exchange of protons on the metabolite with matrix protons (uric acid) [117]. It is also useful for tracking metabolite pathways.

10.3 ANALYTICAL PLATFORM

Once the study is designed and the type of experiment to be performed has been selected, it is important to determine the analytical platform. When selecting a platform for metabolomic analysis, it is important to consider its benefits and limitations prior to designing the study.

10.3.1 Nuclear Magnetic Resonance

The advantages of using nuclear magnetic resonance (NMR) for metabolomics are as follows:

- It is nondestructive and selective.
- Sample preparation is simple.
- It can be used for absolute quantitation.
- It provides information on structure
- It is independent of analyte polarity.
- It can be high-throughput and automated (associated with cost reduction).
- It can be considered an almost universal detector [118,119].
- The spectra are highly reproducible for most sample types; urine is more variable.

One-dimensional NMR is very fast, and no chromatographic preseparation or sample derivatization is required.

NMR metabolomics is also highly suitable for large-scale cohort and similar studies. Perhaps the most unique and important feature of NMR is that is can be used to identify novel compounds (generally accurate mass MS to obtain the molecular weight and 2D NMR methods are required) [120]. NMR spectroscopy is a technique that exploits the magnetic properties of atoms in order to obtain information about the structure of a molecule, and hence its identity. With its powerful quantitation capabilities [121], it is highly suited to metabolomics.

NMR detects nuclei that spin when placed in a strong magnetic field. The spin is either aligned with the magnetic field (spin-up) or opposed to it (spin-down). The nuclei in the spin-up state are in the low-energy state; those opposed to the magnetic field are in the high-energy state, as energy is required to oppose the magnetic field. Electromagnetic radiation, in the form of radiofrequency (RF) pulses, is used to push some of the nuclei in the low-energy state into the high-energy state. Once the pulse has been stopped the nuclei relax back to equilibrium. The energy is returned in the form of free induction decay (FID). These signals result from oscillation of the nuclei, which decays with time. The NMR instrument acts as both a radio transmitter and a radio receiver. The FID can be Fourier-transformed in order to convert the time domain into the frequency domain. This allows the data to be interpreted [122] (see Figure 10.3 for an example of a typical NMR spectrum of plasma using a CPMG pulse program, discussed later).

The most common nucleus observed in NMR experiments is the proton (^{1}H). Proton NMR allows absolute quantitation. It can detect almost anything with ^{1}H nuclei, including amino acids, carbohydrates, carboxylic acids, and so forth, provided it is in a high enough concentration.

There is a high abundance of hydrogen in metabolites, and NMR is very sensitive to proton signals [119]. Other commonly observed nuclei are carbons (^{13}C) and nitrogens (^{15}C) [121].

The RF must be exactly equal to the energy gap between the spin-up and spin-down states. Therefore, the higher the magnetic field strength (Tesla), the larger the difference in energy (MHz) between the two spin states (up versus down), resulting in better resolution. Sensitivity also increases with increased magnetic field strength [118]. For example, an increase from a 14.1 T/600 MHz magnet ($14.1^{3/2}=52.9$) to a 16.4 T/700 MHz magnet ($16.4^{3/2}=66.4$) results in an increase in sensitivity of 1.25 (66.4/52.9).

The first step of an NMR experiment is to design the pulse program. There are numerous predesigned sequences available with NMR software. These can be chosen from the catalog depending on the type of experiment you wish to perform and can be adapted to suit your sample type, solvent type, research question, and so forth.

A detailed guide to NMR pulses is outside the scope of this chapter. The basic pulse program begins with a delay (as this pulse will be repeated multiple times). A 90 pulse is then applied to transfer the magnetization from the z-axis to the x-y axis, where it can be observed, and to push the nuclei from the low- to the high-energy state. This is followed by the acquisition period, where the signal emitted by the precessing nuclei is recorded [121].

10.3.1.1 NMR Instrumentation

A typical NMR spectrometer setup consists of a superconducting magnet, a probe, a console, and a computer. The superconducting magnet is often a solenoid made from nobium titanium alloy. A large current flows around the loop, creating the strong continuous magnetic field required to align the nuclei. The magnet must be kept extremely cold, 4.3 K (−268.85 °C), to maintain minimal resistance (i.e., to continue acting as a superconducting magnet). This is achieved by maintaining the magnet under liquid helium in a vacuum jacket. As liquid helium is expensive and stocks are diminishing, an outer jacket containing liquid nitrogen is generally used in addition.

The sample is placed in an NMR tube and dropped into the magnet on a cushion of compressed air. The strong magnetic field causes the nuclei to become aligned or opposed to it.

The pulse program parameters are sent to the console. From here the required RF pulses are transferred to the probe. The probe is positioned in the middle of the magnetic field and contains the RF coils that go around the sample. It transmits the required RF pulses to excite the sample. It also acquires the weak FID from the nuclei in the excited sample. This is amplified and converted from an analog to a digital signal before the data are sent to the computer. Here the data can be manipulated (Fourier-transformed, phased, etc).

10.3.1.2 Experimental Techniques

Preanalytical Factors

To minimize artifacts and bias due to variation in sample collection, handling, and storage, standard operating procedures should be followed [90,123]. Care should be taken to avoid prolonged venostasis or contamination with ethanol or other substances used to clean the skin. For patients on IV drips or total parenteral nutrition, the arm with the drip in it should be avoided [19]. For toxicological metabolomics studies, consideration should be given to when the drug was administered. Fasting samples are generally recommended, as dietary intake can cause significant variation in metabolites. Time of day of sample collection should be consistent, as many metabolites, including cortisol, are subject to diurnal variation [19,123]). Where possible, multiple measures from the same patient should be used to give an average baseline.

Tube types should also be standardized. A comparison study [123] showed that the differences in NMR metabolite profile of serum compared to plasma (collected in heparin tubes) was minimal. Plasma samples collected in EDTA tubes results in huge contaminating peaks in ^{1}H NMR spectra, corresponding to free EDTA, magnesium EDTA, and calcium EDTA complexes. These peaks can potentially obscure the resonance signals of other metabolites. However, the influence of EDTA contamination was investigated and it was found that metabolites with resonances at these chemical shifts have other chemical shifts in areas not affected by EDTA and so they can still be identified and quantified [124].

For urine samples, 24 h timed urine collections are better as outputs can be normalized to time. The 24 h urine volume should be recorded and assessed for complete collection (a low urine volume may suggest an incomplete collection).

The time before centrifugation (serum-clot contact time) should be standardized. It has been found that this was the preanalytical factor, after interindividual variation, that caused the most variation in results [123]. Clotting on ice reduces this effect and is recommended [123]. There must be enough time (approximately 30 min) to allow the sample to fully clot but not so much that changes accumulate due to continued metabolism of glucose.

As much information as possible should be recorded with the sample: time of collection, time of centrifugation, temperature, time before freezing, and so forth [90,123]. Freeze–thaw cycles should be minimized by aliquoting the sample into multiple tubes. One freeze–thaw cycle has only a small affect, but multiple freeze–thaw cycles can significantly affect the metabolite profile [90,123].

Sample Preparation

For serum samples, proteins and lipoproteins can interfere with metabolite quantification; they can be removed by protein precipitation, solid-phase extraction, liquid-liquid extraction, or spectral filtering [118,125]. If not removed, they can result in variation in analytes and in analyte loss [118]. The alternative, spectral subtraction, where the sample background is subtracted, can also cause signal loss and distort the spectrum [118].

Deuterium oxide (D_2O) for locking the signal, pH buffer to minimize shifts due to pH, imidazole as a pH indicator, and azide as a biological and internal standard for referencing the chemical shift and as a quantification standard [70] are often added to each sample prior to analysis. A deuterated solvent is generally used in NMR. The magnetic field can then be locked to the ^2H in the deuterated solvent so that any changes in chemical shift of the metabolites are due to the environment of the protons within the molecule and not simply due to changes in magnetic field strength [121].

While large numbers of samples are waiting to be analyzed by NMR, the temperature should be controlled, as differences in the amount of time at room temperature can result in systematic bias [102,123]. Temperature-controlled sample changers are available for NMR.

10.3.1.3 Common 1D NMR Pulse Programs

One of the most commonly used pulses is the 1D-^{1}H-Nuclear Overhauser Effect Spectroscopy (NOESY) pulse. This is because it is a simple sequence, with few optimization requirements or hardware restrictions and good-quality water suppression is generally easily obtained [126].

The Carr-Purcell-Meiboom-Gill (CPMG) pulse program is used to identify small molecules in the presence of large proteins and lipoproteins [127]. An initial 90° pulse is applied. During the first delay, the spins begin to dephase (the nuclear spins get out of synch over only a couple of seconds). This is due to spin—spin relaxation (T2) caused by the interaction of spinning nuclei with other spinning nuclei. Their spins are different due to differences in the Larmor frequency, differences in the nuclear environment, and tiny inhomogeneities in the magnetic field. A 180° pulse is applied to rephase the spins (fast ones to the back and slow ones to the front). The FID is then acquired. This allows a longer delay between initial pulse and acquisition. Large molecules such as proteins will have stopped spinning by the time the acquisition phase is begun, so only the FIDs of the small molecules, which can spin for longer, are recorded. This pulse program, a form of spectral filtering, is very useful for serum samples, which are full of lipids and lipoproteins.

10.3.1.4 Quantitative NMR

Although NMR is described as a quantative method, errors in quantitation can be caused inadvertently if careful consideration is not given to the acquisition and processing of the samples.

Preanalytical considerations are as above (e.g., freeze—thaw). For absolute quantitation (quantitative NMR, or qNMR) a signal:noise (S:N) ratio of >100:1 is required, whereas only 10:1 is required for relative quantitiation [118]. The number of scans can be increased to increase the S:N. The increase is proportional to the square root of the number of scans added (4 scans = 2*; 16 more scans = 4*; 64 more scans = 8*); therefore, only small improvements are achieved with large numbers of extra scans [119]. A compromise must be made between analysis time and S:N achieved.

Another essential consideration for qNMR is spin-lattice relaxation time (T1). This is caused by the interaction of the nuclei with the surroundings (the lattice). It determines the time taken for the net magnetization (vector sum of the magnetic moments of the nuclei) to return to equilibrium (completely relaxed). Different protons in different metabolites will have different T1s, as they have different rates of relaxation due to differences in the nuclear environment [90]. The temperature and the solvent, because of their effects on viscosity, also affect T1. Carbon T1s are typically much longer than proton T1s. T1s can be measured by the inversion recovery method [128]. After one T1, approximately 63% of nuclei have returned to equilibrium. After five T1s, >99% have returned to equilibrium. For quantitative NMR, the pulse delay (time between pulses) must be at least five times T1 to ensure that the relative peak areas are not underestimated [118].

If this is not possible, incomplete relaxation can be corrected for, providing the T1 times have been measured in the same sample matrix [118].

10.3.1.5 Two-Dimensional NMR

Two-dimensional NMR (2D NMR) is a technique used to increase the resolution of NMR. The data are plotted against two frequency domains: the direct domain (F1), based on FT of the direct time domain (t1), and the indirect domain (F2), based on the indirect time domain (t2) obtained by increasing the delay between multiple 1D spectra. There are many methods for performing 2D NMR such as Correlaction SpectrsocopY (COSY), TOtal Correlation SpectryoscopY (TOCSY), and Nuclear Overhauser Effect SpectroscopY (NOESY). These methods are very important in metabolomics because they help determine which peaks are connected, part of the same spin system on the same molecule, when multiple metabolites are present. It is useful when there is significant spectral overlap in 1D NMR, as it increases signal dispersion. It also allows structural determination of metabolites that are too complex to work out with 1D NMR alone [63,129].

To perform a basic 2D NMR experiment, the 1D spectrum must first be optimized. Hundreds of 1D spectra are recorded, and the delay in the pulse sequence is increased with each acquisition. Resulting spectra are stacked, with the lowest t1 value at the bottom. FIDs of each acquisition are Fourier-transformed as normal to obtain the F2 (direct) frequency spectra. A new FID is formed across the stacks—in the indirect time domain (t2)—which is then Fourier-transformed to obtain the orthogonal F1 (indirect) spectrum. The indirect time domain is a result of the FIDs being sampled at discrete time intervals. F1 and F2 may be plotted against each other to observe cross-peaks [129], which are formed when the frequency of two nuclei overlap. The intensity of each cross-peak is shown on the z-axis in a topographic (contour) plot. It is determined by the efficiency of the transfer of magnetization from an excited nucleus to another, nearby nucleus. The full 2D spectrum represents all the interactions resulting from magnetization transfer: if there are a large number of paired nuclei, there will be a correspondingly large number of cross-peaks. These can then be assigned to specific positions on the metabolite [121]. Quantitation of 2D-NMR spectra is challenging [130].

A typical 2D NMR experiment consists of four stages: preparation, evolution (t1), mixing, and detection. In the preparation phase, a pulse is used to excite the nuclei. An evolution period (t1) is the delay; this is increased by a fixed amount for each pulse. During the mixing time the magnetization is transferred from the excited nuclei to other coupled nuclei within the same spin system via J-coupling or Nuclear Overhauser Effects (NOE). In the acquisition phase, the FIDs produced by the precessing nuclei are detected [129].

There are many different types of 2D NMR experiment. These mainly differ in the pulses and delays used during the mixing time to transfer the magnetization. There are two types of 2D NMR: homonuclear, where magnetization is transferred from one nucleus to another nucleus of the same type (usually ^{1}H to ^{1}H), and heteronuclear, where magnetization is transferred from one nucleus to another nucleus of a different type (usually ^{1}H to ^{13}C) [121].

Two-dimensional COrrelation SpectroscopY (COSY) [121] is a method for performing structural analysis by tracing atomic relationships through closely coupled bonds. Magnetization is transferred via J-coupling. Coupling distances can be 2-bond (geminal), 3-bond (vicinal), or (rarely) 4- or 5-bond (long range).

2D NOESY allows structural determination via relationships between atoms through space. The z-magnetization is transferred via NOE from the excited nucleus to all other nuclei in the same spin system via multiple transfers. Cross-peaks are observed if a proton is less than 5 angstroms away from another proton in the same spin system [121].

Heteronuclear single-quantum coherence (HSQC) [131] correlates proton resonances with 13C or 15N resonances that are directly coupled. This method is improved by derivatized metabolites [118]. For example, ^{13}C-glucose, can be used to perform metabolic flux analysis to identify which metabolic pathways are using the metabolite [118].

J-resolved NMR is one of the simplest 2D NMR experiments [119]. It uses a double spin echo sequence to supress strong coupling artifacts [132], so the peak splitting caused by J-coupling is reduced. This allows spectral overlap to be minimized, making the spectra easier to interpret. The lack of correlation makes J-resolved NMR less useful for structural determination; however, if the metabolites at the chemical shifts of interest are known, this is not a problem. A 2D NMR spectrum is obtained and used to identify J-coupling. The split peaks are removed and the 2D NMR is projected back as a cleaned-up version of the original 1D NMR spectrum, with only singlets [119]. The spectra are optimized and aligned, as in 1D NMR. This method has been shown to aid the identification of small molecules that would otherwise be hidden by the overlap caused by J-coupling in typical 1D NOESY or CPMG pulse programs [119]. Signals from lipoproteins and proteins are also decreased. Metabolite quantification can be more challenging in J-resolved spectra due to alterations in line shape [119,133].

A recently developed method is ultrafast 2D NMR (UF-NMR). It virtually splits the sample into multiple slices and performs a different excitation pulse on each slice. This is termed spatial encoding. Acquisition is performed on the spatial gradients within the sample. It can therefore provide 2D data in a single scan, drastically improving analysis time. Ultrafast 2D NMR has been described in detail [129]. Its benefits include increased throughput or timesaving and minimization of spectrometer instabilities that decrease the reproducibility of typical 2D NMR spectra [130]. This method has been used to look at the metabolite changes (in terms of absolute quantitation) in breast cancer cell extracts [130].

2D NMR is difficult to interpret manually, especially for complex mixtures. 2D NMR spectra may be analyzed using a variety of softwar, for example, Amix (Bruker Biospin, Germany), MetaboMiner [134], or the CCPN Metabolomics Project [135].

10.3.1.6 Other Techniques

Statistical TOtal Correlation SpectroscopY (STOCSY) [136] is used to identify correlations of spectroscopic signals with other signals. The 1D spectra of many biological replicates are compared. Peaks from the same metabolite are statistically correlated—even across multiple spin systems. Therefore, if individual peaks increase and decrease by the same magnitude as other peaks in the same sample in each replicate, it can be inferred that they are from the same metabolite, or from the molecules regulated by the same metabolic pathway [63,68].

Statistical HeterospectroscopY (SHY) [137] is used to correlate peaks from MS and NMR (or any two or more independent spectropscopic methods). Again, multiple biological replicates are analyzed by MS and NMR. If the increase or decrease of a peak is statistically correlated across the two methods, it can be inferred that they are from the same metabolite or from metabolites belonging to the same biochemical pathway [63,68].

NMR Hyphenation

Although one of the advantages of NMR is that sample preseparation is not required, separation can help in cases where a low-abundance metabolite in a sample otherwise full of high-abundance metabolites is of special interest. Generally, NMR is hyphenated to an LC system, LC-NMR. This is a technically demanding technique, as it is very difficult to shim the sample, which can result in poor spectra. Another method is simply collecting fractions from an LC using a fraction collector and running individual fractions on the NMR. Solid-phase extraction is often required before NMR spectroscopy of the fractions, as the ionic strength or pH can affect the results.

The samples can also be split so that one part is analyzed by MS and the other by NMR [63]. Depending on the MS method used, this allows determination of the exact mass, which can be used to deduce the molecular formula. Information from the retention time can also be used to putatively identify the compound. The NMR is then used to confirm the structure of the compound using the molecular formula and spectra obtained. This can be very important when cohort MS detects a metabolite that is consistently up- or downregulated in cases versus controls, but cannot be identified confidently with MS alone.

Water Suppression

The majority of samples and solvents used in metabolomics contain a large amount of water. For example, serum and urine are approximately 95% water [125]. The water signal must be suppressed or it will swamp all the other signals and can cause radiation damping [63]. There are a number of water suppression methods available that allow higher receiver gains to be used, resulting in greater sensitivity [118]. Presaturation of the water signal, the most common, is generally achieved using a long low-powered pulse at the frequency of the solvent [118]. Water suppression Enhanced by T1 (WET) and WATER suppression by GrAdient-Tailored Excitation (WATERGATE) and excitation sculpting use gradient pulses to suppress water [118,138].

Care must be taken in the quantitation of peaks close to solvent peaks, as their resonances may have been suppressed along with the solvent suppression or there may be baseline distortions resulting from the suppression [118].

10.3.1.7 *Optimization of Detection*

Acquisition time should be optimized to be short enough to prevent excess noise and long enough that the FID is not truncated [118]. The digital resolution (number of data points per Hz) should be high enough that there are at least five data points for each peak of interest [118]. Zero filling (adding zeros to the end of the FID) can be used to increase the number of data points without increasing noise [118,121]. This can allow fine coupling to be detected but can result in artifacts in the spectra. The baseline should be flat, corrected to zero, and the spectra must be properly phased in order to obtain accurate integration [118,121]. Alignment of the spectra may also be required to compensate for drift due to matrix effects [90].

10.3.1.8 *Limitations of NMR*

In comparison to mass spectrometry, NMR is less sensitive. The amount of pure material required in order to obtain a decent S:N ratio depends on the type of probe and the magnetic field strength. The probes used in metabolomics are generally cryoprobes, where the detector and preamplifier are cooled to approximately 20 K [71]. Cryoprobes have up to four times the S:N compared to room-temperature probes because the detection sensitivity of the RF coil is increased and thermal noise in the electronics is reduced [63,71,118]. Microcoil probes can also be used with small-diameter NMR tubes to increase sensitivity and are especially good for limited sample amounts [63,71,118]. The pulse is repeated multiple times on the sample in the magnet to increase the S:N ratio. For good peaks that can be used for quantitation, the sample must be carefully shimmed. A series of electromagnets are used to adjust the magnetic field in order to maximize the homogeneity of the magnetic field. This is essential for obtaining sharp peaks. If the magnetic field is poorly shimmed, the chemical shift of the nuclei will vary across the sample due to local changes in the magnetic field, resulting in broad peaks that could overlap with other peaks and be difficult to identify or quantify [121].

10.3.1.9 *Spectral Overlap*

Proton NMR is limited by the small chemical shift scale (0–10 ppm for the majority of compounds). 1D 1H NMR of mixtures can be extremely difficult. Each metabolite will have multiple signals for each proton in a different environment. Multiple signals are also obtained for stereoisomers of slowly interconverting conformations. Due the multiplicity of signals from many metabolites, NMR of mixtures can result in significant signal overlap. To overcome this problem, 2D methods can be used, but they take much longer to perform (hours compared to minutes for 1D NMR) because of the number of scans required. J-resolved NMR has the benefit of minimizing spectral overlap in a much shorter time than other 2D NMR methods [119].

10.3.1.10 *Matrix Effects*

Although NMR does not suffer from the effects of ion enhancement or suppression, as in MS, differences between sample matrices will still affect the spectra. Subtle differences in pH, ionic strength and protein content cause differences in peak position and line width. Each metabolite is differentially sensitive to these effects. In many compounds, NMR resonances of each nuclei are affected independently—making global correlation extremely difficult.

Such effects can be minimized by careful consideration of sample preparation. For example, mixing the sample with a good buffer will minimize differences in pH between samples, although for urine samples that have a wide pH range, shifts can still be seen even after buffering [63]. Note that the ionic strength of the buffer must not be so great as to adversely affect tuning and matching of the probe [63]. Also, a known concentration of imidazole can be added to act as a pH reference for the sample, as its ppm can be used to determine pH [139]. The NMR should also be regularly temperature-calibrated, for example, with deuterated methanol, to eliminate skew caused by temperature effects [140].

10.3.2 Mass Spectrometry

Mass spectrometry is an analytical technique that essentially "weighs" each molecule in a sample and plots the detected masses on a graph (Figure 10.4).

Mass spectrometers commonly used in the life sciences range from low-resolution quadrupole mass filter [141] and quadrupolar ion trap [141] instruments to high-resolution time-of-flight [142,143], orbitrap [144], and ion cyclotron resonance [145] instruments. High-resolution instruments are also those with the highest mass accuracy, but both high- and low-resolution instruments are commonly used in metabolomics applications. High resolution allows us to distinguish between, for example, tyrosine ($C_9H_{11}NO_3$, with a protonated monoisotopic mass of 182.081) and methionine sulphone ($C_5H_{11}NO_4S$, with a monoisotopic mass of 182.048) because they appear as two separate peaks (Figure 10.5). On a low-resolution quadrupole instrument, these peaks overlap and appear to be a single peak. High mass accuracy, on the other hand, provides the capability to calculate the empirical formula of a compound, based on its mass defect—that is, its deviation from unit mass resulting from the presence and number of heteroatoms in the structure, often supplemented by the intensity ratio of detected isotopes [146,147]. While this is not infallible, especially when including a wider variety of possible atoms than C, H,

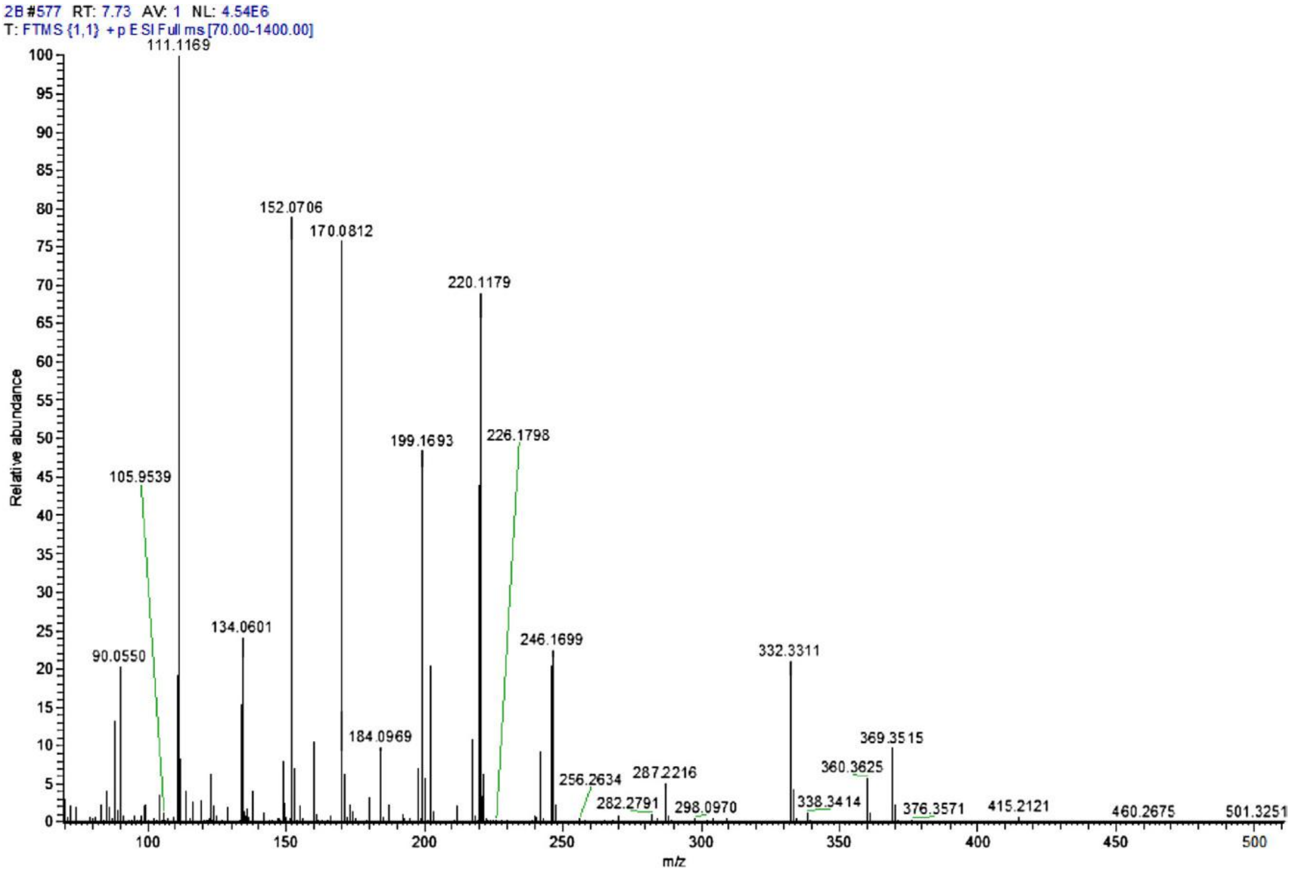

FIGURE 10.4 **Typical mass spectrum from a metabolomics experiment.** Each fine vertical peak is a detected metabolite. Mass:charge ratio is displayed along the x-axis, and relative abundance is plotted on the y-axis. Peaks are labeled with their constituent masses. The spectrum, despite being a single data point from a section of an LCMS analysis, is very complex.

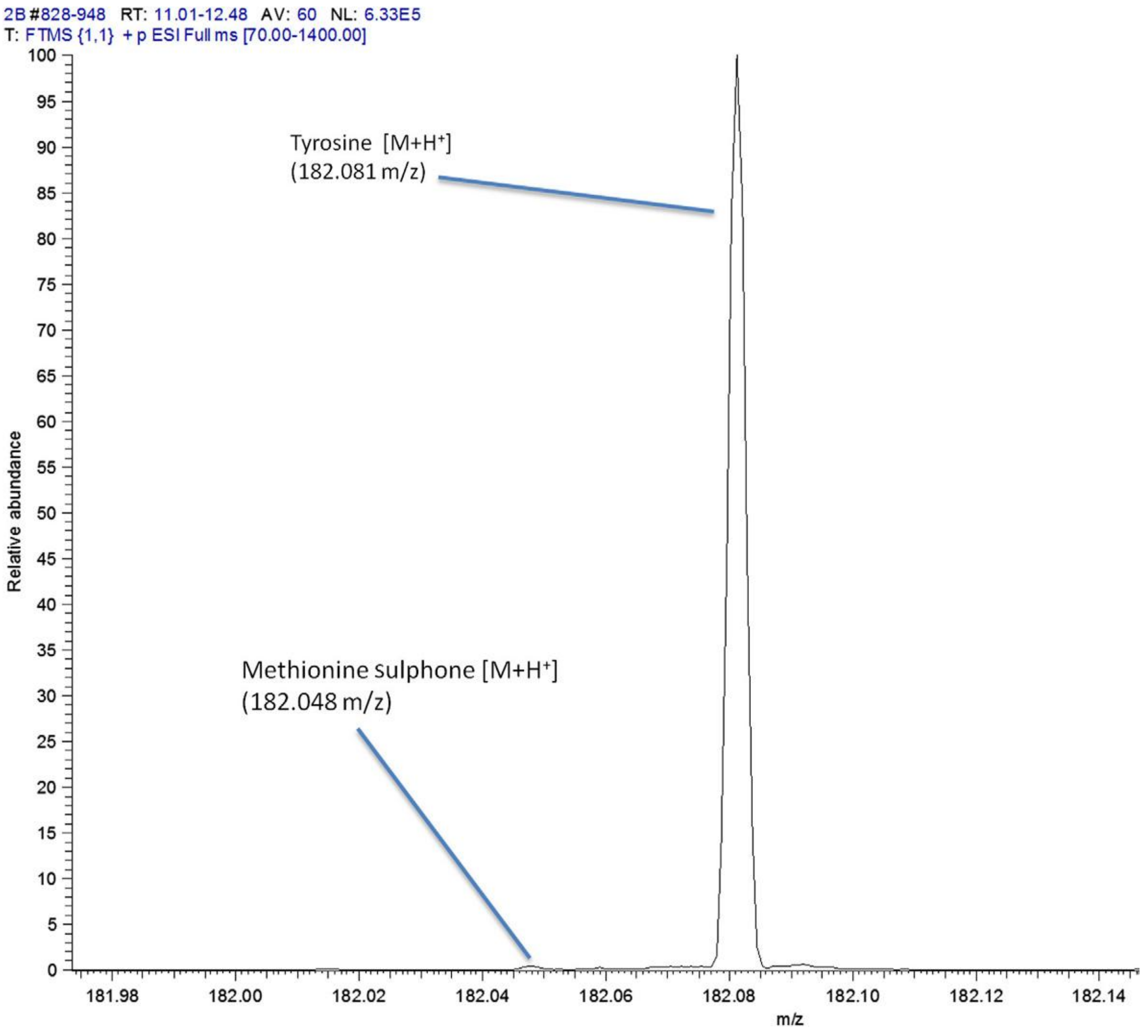

FIGURE 10.5 Compounds with similar mass. Tyrosine ($C_9H_{11}NO_3$, with a protonated monoisotopic mass of 182.081) and methionine sulphone ($C_5H_{11}NO_4S$, with a monoisotopic mass of 182.048). While methionine sulphone is very low intensity compared to tyrosine, it is still a distinct peak. A resolving power of 50,000 is amply sufficient to distinguish these compounds. Unit mass resolution quadrupole instruments would display a single peak in this instance.

O, and N [148], it is a powerful method for narrowing down the search space of possible metabolite identifications. Due to their high resolution and mass accuracy, these instruments are normally used in an untargeted manner, where an effort is made to detect, annotate, and quantify every available peak in a sample.

Unit mass resolution instruments, such as quadrupole-based mass spectrometers, often apply fragmentation to generate orthogonal information that can help them approach the diagnostic capabilities of accurate mass instruments. Of course, these fragmentation techniques are also available for high-resolution instruments for confirmation of identification. In the most common use of this type of experiment, a multiple reaction monitoring (MRM) [149,150] experiment is carried out on a triple-quadrupole instrument [151].

MRMs are based on the application of quadrupolar mass filters to exclude any ion that does not possess the appropriate unit mass. Once an ion of particular mass passes the first quadrupole, it is fragmented in a second quadrupole before the resulting fragment ions are filtered in a third quadrupole (thus, the “triple-quad” instrument type). Only ions passing through both filters strike the detector and are analyzed (see Figure 10.6). For this reason, MRM experiments are extremely sensitive and, if unique fragment ions for a particular structure can be obtained, can also be very specific. The significant drawback to this technique is that it can only be used in a targeted manner: if the experiment does not

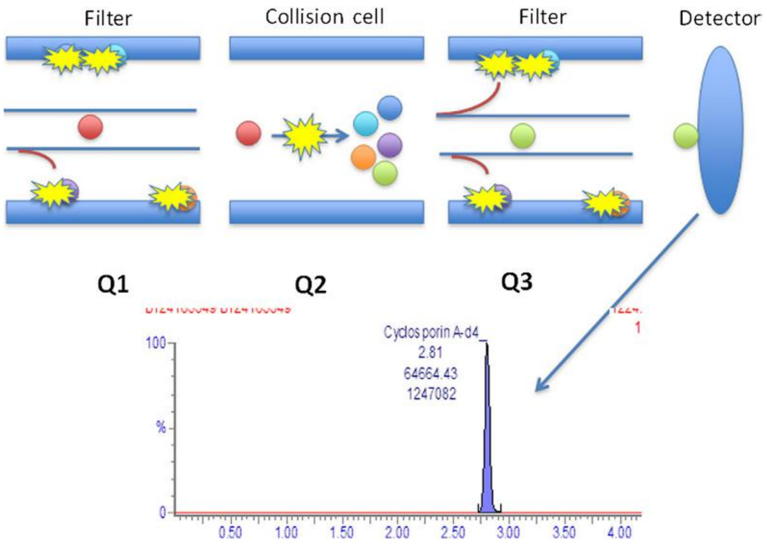

FIGURE 10.6 Multiple reaction monitoring experiment using a triple-quadrupole mass spectrometer. It was used for selective and sensitive detection of specific compounds. In this instance, the intact mass of cyclosporin is selected for quadrupole 1 (Q1), then fragmented in quadrupole 2 (Q2). The resulting ions are filtered to exclude nondiagnostic fragments in quadrupole 3 (Q3). Diagnostic fragments are allowed through the filter to strike the detector, producing a peak at the appropriate retention time in the chromatogram.

apply a particular MRM designed for a specific molecule, the molecule will not be detected.

10.3.3 Liquid Chromatography–Mass Spectrometry

Two significant drawbacks to any mass spectrometry method are isomers and ion suppression. Isomers will be discussed in more detail in Section 10.3.3.2; they are compounds with identical chemical formulas (and therefore mass) but different structures. Ion suppression (whose implications in clinical analysis are reviewed in reference [152]) occurs due to a variety of factors, predominantly modification of the solvation characteristics of the sample by an eluting compound. For this reason, it is considerably advantageous to apply a separation upstream of the mass spectrometer and usually directly coupled to it. Liquid and gas chromatography are the most commonly used methods for separating compounds prior to their introduction to the mass spectrometer. Both are based on the transient interactions of analytes with a surface (the stationary phase) while carried by a mobile phase (either a liquid or a gas). Analytes that interact strongly with the stationary phase will elute more slowly than analytes that interact weakly or not at all.

Reversed phase chromatography is the most common separation technique for LC-MS metabolomics [80,153]. It separates on the basis of hydrophobicity, so nonpolar compounds are eluted more slowly than polar compounds. Newer, but gaining more acceptance, are HILIC separations, which separate compounds on the basis of hydrophilicity and are more selective for polar compounds [72,73,154].

10.3.3.1 Sample Preparation for Liquid Chromatography–Mass Spectrometry

A significant consideration with any analytical technique is the requirement for sample preparation. Mass spectrometers are sensitive to contamination and interfering compounds, and liquid chromatography can be fouled by the use of incorrect buffers. There are, essentially, three methods for the extraction of metabolite samples: extraction of the metabolites followed by introduction of the extract to the chromatography system; extraction of the metabolites followed by lyophilization of the extract, resuspension in a suitable solvent, and introduction to the chromatography system; and cell lysis: solid-phase extraction to enrich for a particular class of compound and then processing in a manner similar to the other two methods. Exhaustive studies have been performed on optimal sample preparation methods for different sample types [155–157].

10.3.3.2 Limitations of Liquid Chromatography-Mass Spectrometry

Any analytical technique has limitations. In metabolomics, complete coverage of the metabolome is as yet not achievable. In addition to this global limitation, each platform for metabolomic analysis possesses a number of drawbacks. For critical evaluation of data, it is important to consider these drawbacks in data interpretation.

Dynamic range is a major issue in metabolomics in that the best mass spectrometers currently have a dynamic range of approximately four orders of magnitude. Given that the most abundant metabolites in a sample have millimolar concentrations (e.g., glucose has 3.5–9 mM), the minimal abundances of detected metabolites will run to the tens of micromoles while the physiological abundances of some compounds, for example, oestradiol, are in picomolar concentrations. MS sensitivity also plays a large part in dynamic range, as we will see later. It may therefore be necessary to further extract low-abundance compounds from the greater metabolome to allow detection of some classes of metabolites. Steroid hormones, for example, are generally at low levels, which makes them challenging to detect in a complex mixture.

Many compounds are labile, rapidly processed by enzymes, subject to oxidation by the atmosphere, or react chemically with other compounds in the metabolite mixture. Labile compounds such as ATP break down over relatively short periods, whereas others, like amino acids, may remain stable for months in solution. Some compounds are extremely rapidly turned over by enzymes [158]. Glycolysis is heavily optimized to rapidly process glucose to the point where at even one second post-lysis, glucose concentrations will have changed dramatically. It is therefore essential to inhibit enzymatic activity as quickly as possible without compromising the experiment, either by snap-freezing aliquots of sample or by the direct squirt method, where samples are simply pipetted, along with medium, into a cold extraction solvent. The latter obviously has the drawback that the signals from the medium will swamp the same metabolites in the cells.

While it is possible in some ways to perform extractions under a nonoxidizing atmosphere, LC-MS instrumentation is not commonly kept in an inert atmosphere and consequently the samples will still oxidize while they are waiting to be analyzed and even during separation. Glutathione and reduced glutathione are particularly prone to oxidation. Derivatization of these compounds to prevent oxidation is possible (e.g., reference [159]), but cannot be applied on a global compound basis.

Heterogeneity of metabolites was mentioned previously, but it is a significant issue for metabolomic analysis. Simply, metabolites are chemically highly diverse, so not only is there no single separation system capable of effectively retaining every metabolite; there is no mass spectrometry ionization mode capable of detecting every metabolite. Electrospray ionization [160] is soft and therefore produces molecular ions of many species, but compounds such as benzene or naphthalene will only ionize via LC-MS using atmospheric-pressure chemical ionization or photoionization [161], which is very limited for higher-molecular-weight metabolites.

Isomers are arguably the most significant problem in metabolomics. Isomers are compounds with identical empirical chemical formulas but different structures: examples are leucine and isoleucine and the hexose sugars, including glucose, fructose, and mannose. While biological samples are often known to contain only a handful of potential isomers, public chemical databases normally contain many more. These are unlikely to be present in biological samples, but they cannot normally be ruled out. There are several effective ways to distinguish between chemical isomers, but each has its limitations and there is no single effective method for distinguishing between all isomers. The most commonly applied mechanism is chromatography.

Specific chromatographic methods exist to distinguish between hexose and pentose sugars [162], sugar phosphates [163], D- and L-amino acids [164], and a plethora of other compounds. These methods are, unfortunately, specific to that group of compounds, and general methods for separating metabolites (most commonly based on reverse-phase and HILIC chromatography) are unable to separate any but the most chemically different compounds. Currently there is a growing interest in ion mobility spectrometry in the metabolomics community [165]. Ion mobility spectrometry (IMS) (see review in reference [166]) is a gas-phase method for separation of ions by charge and cross-sectional area. It is very rapid (usable in chromatographic time as an additional dimension of separation) and may be used, given a suitably high-resolution drift cell, to distinguish isomers.

The other common method for distinguishing isomers is fragmentation. Several mass spectrometry methods are available for isolating a molecular ion and breaking it into component fragments. The most common is collisionally induced dissociation (CID) or collisionally activated dissociation (CAD), which is a technique that applies thermal decomposition to a molecule. CID is usually deployed in the form of a quadrupolar collision cell or in an ion trap instrument. The former is generally a harder fragmentation than the latter, producing more small fragments. CID in an ion trap has the unique property that it can be performed in rounds, such that a precursor ion can be selected and then fragmented to produce a spectrum of fragment ions, followed by selection of a fragment that can then be fragmented, and so on. Needless to say, MS_3 (i.e., a survey scan, followed by two rounds of fragmentation) or higher provides clearer structural determination than a single round of fragmentation [120,167], but it takes longer and requires more samples. In some cases the use of MS_3 or greater is still unable to distinguish some isomers.

Sensitivity and detection limits in mass spectrometry are molecule-dependent. Certain groups, such as amines or carboxylic acid groups, are easy to ionize in a suitable buffer. Other compounds, such as uncharged molecules, aromatic species, and aldehydes, are challenging to ionize under normal conditions. Overall ionizability is determined by the totality of interactions between functional groups in a molecule. For a given amount of a compound, the signal intensity in the mass spectrometer is dependent on its chemical structure [168]. This means that the intensity of a peak for one compound is not comparable to the intensity of a peak for another compound. Relative quantitation may be performed by comparing the intensity of a compound in one sample with the same compound in another sample, assuming that matrix effects (such as ion suppression) do not compromise the signal of either peak. For absolute quantitation, it is necessary to provide a compound with identical physicochemical properties but different mass (i.e., an isotopically labeled compound) as an internal mass standard [169].

The chromatograms produced by a typical LC-MS run are highly complex. Metabolite samples, as previously described, contain hundreds to thousands of individual metabolites. This complexity is enormously enhanced by the presence of adducts and fragments [170]. Electrospray ionization, the most common method for providing a charge to a compound in biomolecular mass spectrometry, generally provides a charge by adding a proton (for positive ions) or removing one (for negative ions). Thus the proton is the simplest and most prevalent adduct in mass spectrometry. The presence of salt in the sample, however, can provide other cations to function as charge donors. Na^+, NH_4^+, and K^+ are common adducts in blood samples analyzed on systems using high-pH ammonium buffers. Electrospray ionization is relatively nondestructive in comparison to competing ionization technologies, such as electron impact ionization or atmospheric-pressure chemical ionization (APCI).

Despite this, it is very common for labile compounds to decompose during ionization. The most common losses include H_2O, PO_4^{2-} (especially from triphosphate compounds such as ATP), CO_2, and NH_3. Compounds can also dimerize in the ion source, leading to a compound double the size of the original. Additionally, it is possible for compounds to obtain multiple charges by picking up two or more protons or other cations. Spectra are further complicated by multiple adducts combining two or more of the previously described events.

An alternative methodology for metabolomics is GC-MS, which is very complementary to LC-MS and NMR platforms.

10.3.4 Gas Chromatography–Mass Spectrometry

The popularity of GC-MS is due to its high chromatographic resolution, reproducibility, high throughput, and low equipment cost. Figure 10.7 shows the separation of metabolites found in orange juice, with the most abundant peak in the chromatogram matching with the library spectrum for sucrose. The most popular method for ionization of the analytes eluting from the GC column is electron impact (EI). This is a high-energy process, resulting in the majority of molecular species fragmenting into product ions. The measured EI fragment spectrum detected by the mass spectrometer is, however, highly conserved over a wide variety of analyzers and manufacturers. The apparent lack of an identifying molecular ion is made up for by a fingerprint fragment pattern that can be matched to spectral libraries.

The most comprehensive and widely used spectral libraries are those provided by the NIST database, which contains spectra for thousands of pesticides and environmental pollutants, drugs of abuse, explosives, and clinical diagnostic molecules, among many, many others [171]. The main spectral library in the current release contains spectra from over 200,000 compounds, each having been verified by expert mass spectrometrists. This makes it possible to use GC-MS to make confident molecular identifications even in the absence of a pure standard. The Golm

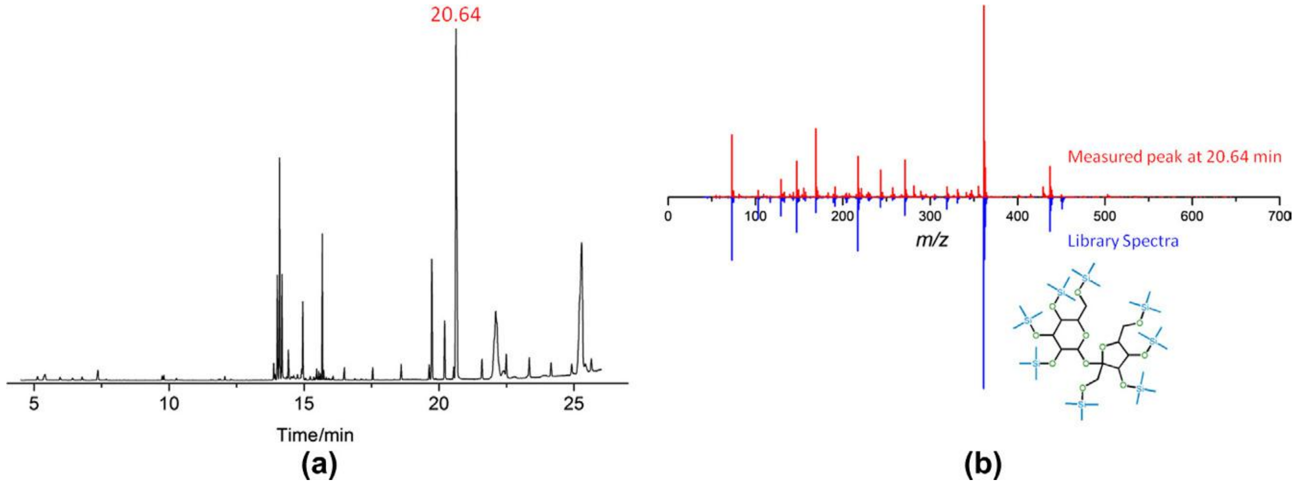

FIGURE 10.7 **Gas chromatography–mass spectrometry.** (a) GC-MS TIC for methanol extraction of orange juice derivitized with MSTFA and separated using a TraceGold TG-5MS (30 m × 0.25 mm ID, 0.25 µm film thickness; Thermo Scientific) in a Trace Ultra GC (Thermo Scientific) coupled to a ITQ 900 MS (Thermo Scientific). (b) EI mass spectrum at 20.64 min matching to the NIST library spectrum of octakis(trimethylsilyl) ether of sucrose.

Metabolome Database (GMD) is a GC-MS spectral library containing biologically active metabolites created by the scientific community [172]. Once a peak has been identified, a targeted method using single-ion monitoring (SIM) or multiple-reaction monitoring (MRM) can be used to increase sensitivity to achieve lower limits of detection (LoD) resulting in lower and more reproducible limits of quantification (LoQ). The addition of an internal standard, usually a deuterated labeled compound of interest, is used as a reference for quantitation [57,173].

10.3.4.1 Limitations of Gas Chromatography–Mass Spectrometry

To be compatible with GC-MS analysis, samples must be dissolved in a volatile solvent. The component molecules need to be volatile and thermally stable to be separated and detected. Many biomolecules contain polar functional groups such as alcohol (–OH), amide (–CONHR), amino (–NH2), carboxyl (–COOH), thiol (–SH), and enolizable ketones. Chemical derivitization results in the substitution of the acidic hydrogen, leading to a decrease in intermolecular interactions [174,175]. The derivitized compounds have an increased volatility, allowing samples that would decompose at high temperatures to be suitable for GC separation at moderate temperatures, and elute within the temperature limits of the column. The reduction in polar interactions with the column also results in better peak symmetry and resolution. Three classes of derivitization agents are silylation, acylation, and alkylation. The selection derivitization agent will depend on the compounds in the sample to be analyzed. This selection can be well known from the literature for a targeted compound, but the correct reagent may not be obvious for an unknown mixture when performing a global qualitative metabolomic analysis.

Silylation is the most commonly used derivitization reagent because these chemicals will react with both –OH (alcohols, carboxylic acids) and –NH (aminos and amines) [176], making them useful for mixtures of compounds with a biological origin. This also requires that the samples be dry in order to be free of water that would also react with the derivitization agent. Metabolite extraction and subsequent purification and derivitization can be very time-consuming. For urinary estrogens, this can involve days of sample preparation using multiple solid-phase extraction cartridges, enzymatic hydrolysis, and size exclusion chromatography as well as chemical derivitization [177]. In such cases a simpler LC-MS methodology may well be desirable.

The fragmentation pattern resulting from EI ionization can make identification of components simple if the spectrum matches a compound in the spectral library. However, this can be far from trivial if there are no high-quality matches or when compounds co-elute, resulting in a mix of fragments from both compounds. Co-elution of compounds can be overcome if there is a spectrum of a pure standard to identify which unique fragment ions are produced from the molecular ion. These unique ions can then be selectively filtered using SIM or MRM to detect only ions that confirm the identity of the eluting compound. Without a pure standard as a reference, identification of unknown compounds can be difficult, especially when there is no certainty that the molecular ion has been detected.

An experienced mass spectrometrist can interpret common fragments and use predictive tools to aid in identifying the molecule; however, this is very time-consuming and not feasible for global metabolite profiling, which can involve hundreds or thousands of unknown compounds. Chemical Ionization (CI) is a slightly less energetic process that leads to fewer, larger fragments and may allow the molecular ion to be observed, but this is not guaranteed. Some compounds, especially those with halogens or that have been derivitized with fluorine reagents, can be selectively detected using negative (−ve) CI, simplifying a complex mixture for simpler interpretation [178–180].

10.4 ANALYSIS OF METABOLOMIC DATA

10.4.1 NMR-Based Metabolomics Data

In 1D NMR, the Fourier-transformed data are represented as a spectra with chemical shift (δ) along the x-axis and intensity along the y-axis. The chemical shift is generally depicted as parts per million (ppm) rather than hertz (Hz), as this is independent of magnetic field strength.

An internal standard (IS)—tetramethylsilane (TMS), Trimethylsilylpropionic acid (TSP), 4,4-dimethyl-4-silapentane-1-sulfonic acid (DSS), or their deuterated analogs— is used as a reference for 0 ppm and for determining the signal produced per proton. These molecules are chemically inert, stable, and soluble; have multiple equivalent nuclei resulting in a single sharp peak; are easily removed from the sample after measurement; and have resonances upfield of most organic compounds [181]. Ideally the IS should not evaporate at the temperatures used for analysis and should not be affected by pH or temperature.

The number of peaks present for a pure metabolite depends on the number of different environments the metabolites' nuclei are in. Because the spectra are dependent on the chemical environment of the nuclei within the molecule, NMR is a powerful method for structural determination. The chemical environment includes the shielding effect of neighboring atoms, the saturation of the molecule, and the number of neighbors [121]. The main determinant of the chemical shift is how shielded the proton is from the magnetic field. Electrons have spin; their magnetic vector opposes the overall magnetic field, shielding the nucleus. Therefore, if the electron density of a nucleus is high, the shielding effect will be higher. Electronegative atoms (such as oxygen, nitrogen, and chlorine) deshield the nuclei, resulting in a shift to the left (an increase in ppm, known as downfield). If there is more than one electronegative atom neighboring the nucleus, the deshielding effect is additive [121].

Another affect of NMR is spin-spin splitting, also known as J-coupling, which can be exploited in structure determination. If you have two protons, with different chemical environments, on adjacent carbons, their different spin states can slightly add to or slightly subtract from the overall magnetic field experienced by the other proton nucleus. If one proton is spin-up (aligned with the magnetic field), it will slightly add to the magnetic field strength experienced by the neighboring proton.

Conversely, if it is spin-down (opposed to the magnetic field), it will slightly cancel out the magnetic field strength experienced by the neighboring proton. The neighboring proton will have its peak split into two equal peaks, one at a slightly higher ppm (downfield—due to increased local magnetic field) and one at a slightly lower ppm (upfield) than the peak would be if it hadn't been subjected to these effects. The splitting pattern follows the $n+1$ rule: if a proton has one neighboring proton with a different chemical environment, it will be split in two, as just described. If it has two neighboring protons with a different environment, it will be split into a triplet with a 1:2:1 ratio. This is because 25% of the time both of these neighbors will spin up, adding to the local magnetic field; 25% of the time both protons will spin down, subtracting from the local magnetic field; and 50% of the time one will spin up and one will spin down, canceling out the effect on the local magnetic field.

Similarly, if there are three coupled protons, a quartet is observed (1:3:3:1); for four coupled protons a quintet is observed (1:4:6:4:1). The pattern follows Pascal's triangle. The area of all the split peaks added together will equal the original singlet, so quantitation is still possible. The effect is generally transmitted only through three bonds or fewer. However, coupling can be observed over more bonds if the molecule has a very rigid structure. This can therefore be used to determine the number of neighbors, helping to determine the structure [182]. The peaks are split by J Hz, where J is the coupling constant. This is independent of magnetic field, as it is caused by the magnetic field of another nucleus, not the magnet itself [121].

Chemical shift, intensity, and coupling patterns are used together to identify the metabolites in the sample. If it is suspected that a peak belongs to a certain metabolite, the other peaks known to be present for that metabolite must be observed in the spectrum, unless that part of the spectrum is overcrowded. Metabolite identification is difficult in mixtures. Note that many NMR chemical shifts are dependent on solvent, sample concentration, and other acquisition parameters (see section 10.3.3 on limitations). Metabolite identification is difficult or impossible for the wide variety of minor and trace metabolites, especially organism-specific metabolites. However, for common and abundant metabolites, automatic identification and quantification are possible using the appropriate software.

Quantitation is based on integration of the peaks and comparison with the reference peak intensity (internal standard of known concentration). The number of nuclei that contribute to the signal is also crucial [118]. For example, the ratio of a methylene (CH2) group to a methyl group (CH3) should be 2:3 for a single metabolite. Depending on whether the methyl shift or the methylene shift is used for quantitation (depending on spectral resolution), a different factor will be required.

$$\text{amount of x} = ((\text{area of x} / \text{area of IS}) \times (\text{nuclei in IS} / \text{nuclei in x})) \times \text{conc of IS}$$

The amount of x can be in grams or moles depending on the amount used for the IS. The areas are integrated using NMR software. The number of nuclei for IS depends on the structure (12 for TMS, 9 for TMS and DSS). The number of nuclei for the metabolite of interest depends on the structure and formula of the metabolite and the number of protons contributing to the signal at that specific chemical shift.

10.4.1.1 Spectral Deconvolution and Peak Picking

One method of dealing with overlapping spectra is deconvolution, which mathematically fits a Lorentzian or Gaussian peak shape to peaks suffering from partial overlap. Software that makes use of this method includes MestReNova (Mestrelab Research, Santiago de Compostela, Spain) and ACD/Labs Spectrus processor (ACD/Labs, Toronto, Cananda) [118]. Chenomx (Alberta, Canada) and Amix (Bruker Biospin, Bremen, Germany) both offer compound identification and quantification with reference to spectral libraries [70].

10.4.1.2 Binning or Bucketing

Binning, or bucketing, is a commonly used method for dealing with the crowded spectra obtained from 1D NMR of complex samples [70,118]. In its simplest form, this method involves splitting the spectrum into bins of a specific size (e.g., 0.02 ppm sections) and integrating the spectrum in the bin, regardless of whether it is from a well-defined peak or an area of overlap or is just baseline. This method cannot be used for absolute quantitation, but the integrals of the bins can be compared between samples using chemometric methods and useful information about where in the spectra differences between cases and controls (or similar) are located. Further analysis can then be performed to identify and quantify metabolites in these regions.

Care must be taken in the interpretation of binned data. As discussed previously, variations in ionic strength and pH between samples can cause the resonances of some peaks to be shifted. Slight alterations in shifts are acceptable as long as the new chemical shift stays in the same bucket; if it moves between buckets, a different bin will be increased and the original will be decreased, which can lead to misinterpretation when comparing different samples [118]. This is becoming less of a problem as alignment algorithms improve [119].

A more robust method of binning is adaptive-intelligent binning. In this case the width of the bin is not kept constant, but is adapted to take account of pH- or ionic-strength-induced shifts. It uses local minima to identify the best location to split the bins [118].

10.4.1.3 Data Normalization

Urine samples can vary significantly in the concentration of solutes depending on fluid status or the individual. Many studies use the creatinine concentration in the NMR spectra to normalize the concentrations of other metabolites [70].

The area of the full spectrum can be summed and used to normalize the solutes. However, the abundance of metabolites across different samples is not constant. For example, a diabetic patient may have significant glucosuria, which makes the other metabolites falsely low using this method [118].

By calculating the most likely dilution factor in comparison to a reference spectrum, probabilistic quotient normalization (PQN) can also be used to scale spectra to the same virtual overall concentration in order to minimize changes in NMR spectra [118,183].

10.4.2 MS-Based Metabolomics Data

When using only two-dimensional datasets, such as when using direct infusion mass spectrometry, data analysis is usually performed by binning the resulting spectrum and comparing sets of spectra using multivariate statistics [184]. These sorts of studies are generally applied in a metabolic fingerprinting process, as the lack of separation of isomers and ion suppression make this method challenging for metabolic profiling and pool analysis.

LC and GC MS produces much more complex datasets with three dimensions to consider. Each eluted metabolite will have a mass, intensity, and retention time. MRM data are easier to interpret as they are restricted to specific peaks preselected for analysis. For quantitative analysis, peaks simply have to be integrated and compared between samples or to an internal standard.

In untargeted, accurate mass LC-MS, extracting real metabolite peaks from background electrical and chemical noise is highly challenging; it requires complex chemometric and bioinformatic pipelines to sift, filter, and annotate the raw data [185]. Known metabolites can be relatively easily detected with extracted ion chromatograms (thin slices across chromatographic time, showing a single peak or a small number of peaks for a specific mass-to-charge ratio) (see Figure 10.8), but detecting all the metabolite signals

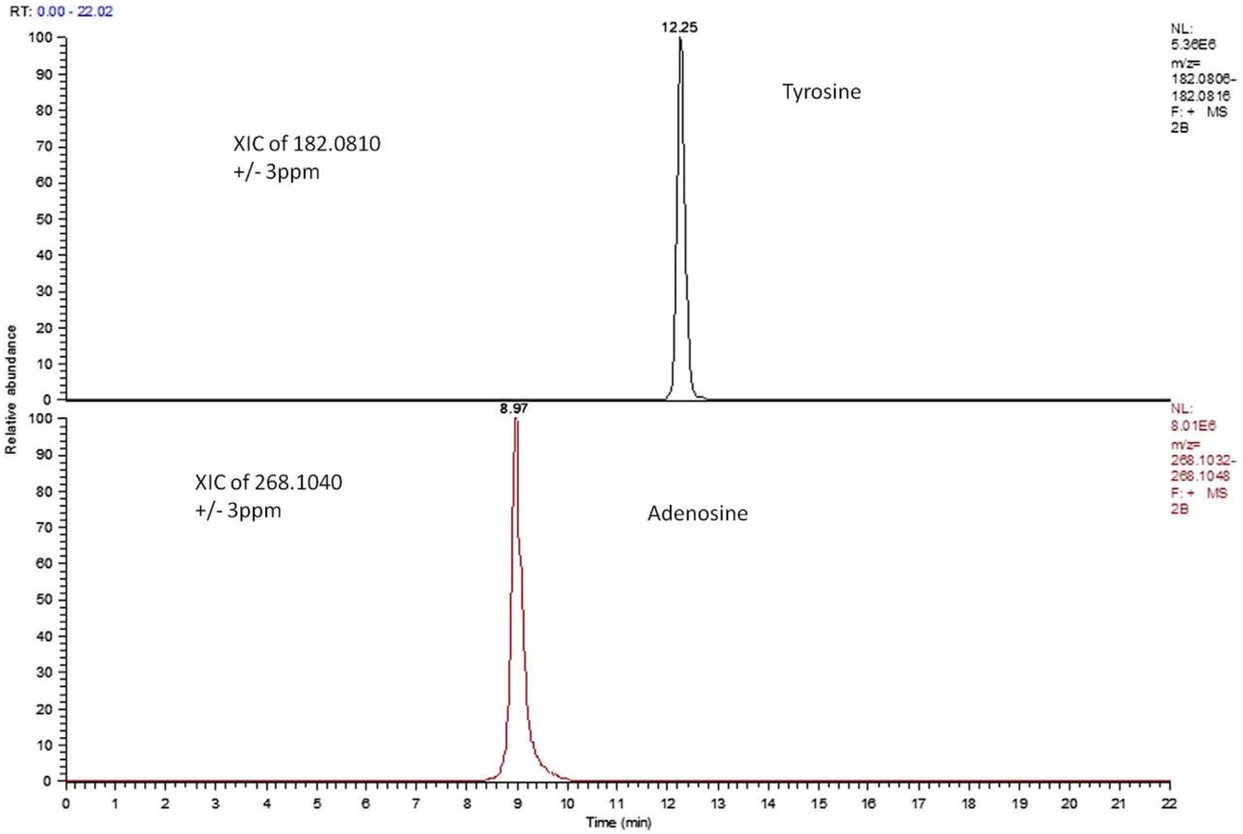

FIGURE 10.8 **Extracted ion chromatogram.** Accurate mass of tyrosine (top) and adenosine (bottom). In these instances, a 3 ppm mass tolerance is sufficient to exclude all other detected compounds from the chromatogram.

requires an unbiased method for peak picking. Several are available, including those incorporated into the XCMS [186], MzMine [187], MAVEN [116], ProGenesis CoMet, and Sieve software packages.

Once peaks are extracted, they must be processed; noisy peaks must be removed; and the entire dataset must be correlated, quantified, and identified. A good metabolomics pipeline must support all of these steps, and many pipelines are available with several alternatives for each one. It is therefore extremely important to apply the correct method for the appropriate data.

Gap filling should be performed on the data. Peak-picking algorithms are not infallible, and often peaks with nonoptimal shapes are excluded in one or more samples from a group. In cases where a peak is detected for some members of a replicate set, it is very valuable to re-search the original raw data for peaks that, rather than not being in the sample, have merely been missed by the peak detection algorithm [185]. At a later point in the processing, missing values should be annotated as n/a rather than 0, as this skews the probabilities for detected values and unrealistically represents the baseline noise level in the dataset. Missing values may also be mathematically imputed given sufficient other samples in each replicate set [188].

Normalization of metabolite data is also extremely challenging, as there are no canonical "housekeeping" metabolites available to perform normalization on. Various techniques have been applied, such as quantile normalization [189], normalization to internal standards [190], normalization to quality control samples [81], and normalization to creatinine concentration for urine samples [191]. In addition to normalization, scaling and log transformation may be applied to metabolomics datasets to reduce the dynamic range of the data and minimize skew in intensity distribution [192].

Due to the high dimensionality of the data and generally the low number of samples compared to the number of variables, it is essential that correction for multiple testing is performed on the data [193], especially if univariate statistics such as t-tests are applied to the data. The most conservative modification to the probabilities is Bonferroni correction [193]; Benjamini-Hochberg [194] correction is a less stringent method for reducing errors due to multiple testing.

10.4.3 Contextualization of Metabolomics Data

Once raw data are translated to a list of quantified metabolites, the most time-consuming and difficult part of the entire metabolomics practice starts: interpretation. Fitting the thousands of detected compounds and hundreds of significantly changing metabolites in a single experiment into a meaningful biological context is extremely challenging.

For fingerprinting analysis, patterns may be generated using multivariate statistical methods such as principal component analysis (PCA) [70], partial least squares discriminant analysis (PLS-DA) [70], or support vector machines (SVMs) [195], which will allow unsupervised (PCA) or supervised (PLS-DA and SVM) clustering of metabolomic data.

When attempting to move to the level of elucidating pathways and networks, however, it is worthwhile to begin by focusing on the most significantly changing metabolites, whether or not they are identified; after all, the most exciting discoveries are likely to be those metabolites that have not as yet been described. In general, it is helpful to examine the metabolic pathways that the compounds fit into. If most metabolites that change in one direction or another belong to the same or related pathways, this is a good indication that this pathway is important to the question being addressed.

There are several pathway-mapping packages available—for example, MetExplore [23], MassTrix [196], Pathos [197], and iPath [198]—which place already identified compounds in their constituent pathways. Pathos and MetExplore can also display up- and downregulation of the particular compounds via color coding in the generated maps. These can be very useful for observing general patterns of change in metabolites.

10.4.4 Annotation/Identification

While many of the metabolites detected may be assigned identities, it is important to classify them as either identifications or annotations depending on the surety of the assignment. According to the metabolite standards initiative [199], only compounds verified by accurate mass, MRM and retention time, or 2D NMR spectral match can be classified as identifications, while those identified by mass or substructure (fragmentation) are categorized as annotations. Although this does not cover all eventualities (especially those situations where retention time and accurate mass are not sufficient to guarantee a single identity matched to a standard), it does provide a reasonable guide to the confidence of an assignment. Of course, heuristics can be applied in context to allow greater confidence: if a number of compounds are detected in the same pathway, with the same direction of change, it is more likely that their identifications are correct.

10.5 CONCLUSION

Metabolomics is a collection of powerful tools for the analysis of phenotype, both by hypothesis generation and by hypothesis testing. Building on the strengths of the "omics technologies that came before, metabolomics uniquely comprises analytical technologies that can provide diagnostic patterns via fingerprinting, absolute quantitation of targeted metabolites via pool analysis, relative quantitation of large portions of the metabolome using metabolite profiling, and tracing of the biochemical fate of individual metabolites through a metabolic system via flux analysis. Each of these technologies is supported by the two most commonly used and powerful techniques currently available for metabolomics: mass spectrometry and NMR.

Mass spectrometry-based metabolomics techniques are the most sensitive for simultaneous analysis of a large number of compounds. While limited in quantitation capabilities without appropriate labeled standards, the sheer quantity of information available in a single LC-MS or GC-MS experiment can provide detailed information on the patterns of metabolite change in an entire metabolic network.

NMR metabolomics complements mass spectrometry. It is limited in terms of sensitivity, but is uniquely capable of elucidating molecular structure. An important additional feature of NMR is that it is quantitative, capable of providing absolute levels of detected compounds when appropriate techniques are used.

Interpreting and deriving context from complex metabolomic datasets are highly challenging and represent a major area of research. Still, great strides are being made in the integration of metabolome data with genomics and proteomics. Metabolomics offers the promise that, in the future, biochemical analysis of the entire path from genotype to phenotype will be measured and explored for new insights into biology and medicine.

11.1 OVERVIEW

Regenerative medicine is a fast developing field of research that aims to contribute new therapies to the treatment of various diseases. Stem cells play a major role in regenerative medicine [1] and human cells are usually the key focus. Human cells come in a variety of types, such as adult stem cells, somatic cells, and the more conventional embryonic stem (ES) cells. These cells can potentially be used to regenerate human cells, organs, and tissues and contribute toward restoration of normal function after disease or injury [2]. The Russian histologist Alexander A. Maximov first proposed the term “stem cell” in 1908, at the annual Congress of the Hematologic Society in Berlin. He coined this term based on the process by which the stem of a tree gives rise to various branches. However, it was not before the 1960s, that scientists realized the potential of these cells.

Stem cells are usually found in multicellular organisms and have the unique capacity for self-renewal. They undergo mitotic cell division and can differentiate into different cell types. During embryonic development, stem cells can form cells of all three germ layers such as mesoderm, endoderm, and the ectoderm. In adults, together with progenitor cells, they can contribute as a repair system for the body as well as maintain the normal turnover of regenerative organs such as blood and skin. This characteristic of stem cells makes them an important tool for potential use in medical therapies [3]. Based on their potency or differentiation ability, stem cells can be divided into five main categories (Table 11.1).

Totipotent Stem Cells. These are stem cells that have a capacity to differentiate into all cell types in an organism, including extra-embryonic tissues. They are usually formed during sexual and asexual reproduction and have the potential to develop into a fully functional embryo and then a fully functional organism. The zygote, which is formed when an oocyte is fertilized by a sperm, falls into this category.

TABLE 11.1 Characterization of Stem Cells Based on Their Potency and Differentiation Potential

Type	Characteristic	Example
Totipotent	can differentiate into all cell types including extra-embryonic tissue, ability to from a fully functional complete organism	cells of the zygote
Pluripotent	can differentiate into all three germ layers, ability to from any of the fetal or adult cell types	ES cells, iPs cells, gPS cells, pES cells, and fetal stem cells
Multipotent	usually consist of progenitor cells, ability to differentiate into only a limited number of cell types	adult stem cells such as HSCs and neural stem cells
Oligopotent	usually consist of cells that reside in the tissue, ability to terminally differentiate into cells of a specific tissue	stem cells present on the mammalian ocular surface
Unipotent	ability to differentiate into a single type of cells	progenitor cells present during postnatal prostate development

Pluripotent Stem Cells. These cells can differentiate into all the three germ layers such as mesoderm, endoderm, and ectoderm. They can differentiate into any of the fetal or adult cell types, but they do not have the ability to form embryos (e.g., embryonic stem cells).

Multipotent Stem Cells. These are usually progenitor cells that are capable of differentiating into only a limited number of cell types. Somatic cells such as neural, bone marrow–derived, or hematopoietic stem cells (HSCs) fall into this category [4].

Oligopotent Stem Cells. These stem cells usually reside in the tissue and can terminally differentiate into cells of a specific tissue [5]. For example, a recent study reported the widespread presence of oligopotent stem cells on the mammalian ocular surface [6].

Unipotent Stem Cells. Unipotent stem cells usually have the ability to differentiate into a single cell type, despite having the property of self-renewal. A recent study successfully highlighted the contribution of unipotent progenitor cells during postnatal prostate development [7].

11.2 STEM CELL TYPES

Based on the previous classification, our body harbors different stem cell types, which are discussed in more detail in the following subsections.

11.2.1 Adult Stem Cells

Adult stem cells are present in fully developed tissues and play a role in maintenance and growth of these tissues throughout their life. They are also termed tissue progenitor cells and are usually multipotent. Adult stem cell or progenitor cell populations are present in many adult tissues such as bone marrow/peripheral blood (hematopoietic stem cells), gastrointestinal tract, brain, skin, muscle, nerve cells, liver, eye, pancreas, and dental pulp [8,9]. They are usually tissue-specific and can only differentiate into cell types associated with the tissue they reside in. They are controlled by their microenvironment or niche [8,10].

Of all the various cell types, hematopoietic stem cells, which are CD34+, are extensively studied and used in therapeutic applications. Exceptions to the tissue-specific characteristic of adult stem cells are the multipotent mesenchymal stem cells (MSCs), which are derived from the bone marrow stroma. They are referred to as multipotent adult progenitor cells and are able to differentiate into a variety of tissues such as neuronal, adipose, muscle, gut, liver, lungs, and spleen, but not bone marrow or gonad cells. They are also able to differentiate developmentally when injected into a blastocyst [8,11]. Adult stem cells are unique in their differentiation ability, such that one type of adult stem cell can differentiate into another type of tissue under suitable growth conditions. This property has been termed as “plasticity” [9].

11.2.2 Fetal Stem Cells

Fetal stem cells are present in the fetus, are pluripotent, and contribute in the initial development of all tissues before birth [9]. They are derived either from fetal tissue or from supportive extra-embryonic tissue; these include umbilical cord blood (UCB), amniotic fluid (AF), Wharton’s jelly, amniotic membrane, and the placenta. As these tissues are normally discarded after birth, their stem cell populations can be used without any ethical concerns. They are similar to embryonic stem cells and multipotent adult stem cells in their capacity for self-renewal and differentiation. Recent studies have come up with various strategies to exploit the therapeutic potential of these cells [12]. Each fetal stem cell type is discussed in more detail next.

11.2.2.1 Umbilical Cord Blood Stem Cells

Umbilical cord blood (UCB) multipotent cells are present in umbilical cord blood. They are genetically similar to the newborn child [9]. Almost 1% of the total population of UCB cells is CD34−, CD34+ (which is a marker for hematopoietic stem cells) and CD38− (which is a marker for immune cells such as white blood cells). These cells have an established capacity for differentiation and self-renewal. Moreover, cord blood is a rich source of MSCs, which support the *in vivo* expansion of HSCs. Cord blood cells, are the second main source of MSCs after bone marrow, and they harbor a subpopulation of cells that express neuronal markers and may act as progenitors of neuronal cells [12,13].

11.2.2.2 Amniotic Fluid Stem Cells

Amniotic fluid (AF) harbors a heterogeneous population of cells from all three germ layers consisting of several partially differentiated cell types and progenitors. These cells are mostly of epithelial origin and are derived from the fetus or the inner surface of the amniotic membrane. AF cells isolated from earlier gestation periods express higher levels of mesodermal and endodermal markers compared to their later counterparts, but the expression of ectodermal markers remains the same. They also contain MSCs and other multipotent stem cells that express stem cell-specific markers such as Oct4 (octamer-binding protein 4), SSEA4 (stage-specific embryonic antigen 4), and Nanog. AF-MSCs are able to differentiate into a variety of cells such as adipocytes, chondrocytes, osteocytes, hepatocytes, neural cells, and cardiomyocytes [12].

11.2.2.3 Wharton's Jelly Stem Cells

Wharton's jelly cells are derived from the outer region of the human umbilical cord, which is known as Wharton's jelly and can be classified into three types: umbilical cord matrix stem cells (UCMSCs), umbilical cord perivascular cells (UCPVs), and umbilical cord stromal cells (UCSCs). UCMSCs are known to facilitate muscle generation; UCPVs lead to a population of MSCs that differentiate into bone nodules, and UCSCs differentiate into several different lineages except neuronal type 1 cells [12].

11.2.2.4 Amniotic Membrane Stem Cells

The amniotic membrane is derived from the epiblast and consists of three layers: epithelial cells (inner layer), mesenchymal cells (outer layer), and an intermediate layer that lacks any cellular component. Since these cells originate from the epiblast, they display several stem cell characteristics and can differentiate into cardiomyocytes, hepatocytes, and endothelial cells *in vitro* [12].

11.2.2.5 Embryonic Stem Cells

Embryonic stem (ES) cells are pluripotent and are derived from the inner cell mass of a blastocyst. That is, they have a capacity for indefinite self-renewal apart from being able to maintain themselves in an undifferentiated or pluripotent state. They also have the unique ability to colonize cells of different lineages, which includes the germline, when they are reintroduced into the blastocyst. Apart from their *in vivo* pluripotent potential, these cells can maintain their ability to self-renew and differentiate *in vitro* [14−16]. ES cells also express the enzyme alkaline phosphatase. They are commonly used and derived from the inner cell mass (ICM) of the blastocyst (Figure 11.1). During embryonic development, ES cells are formed from the cleavage of the zygote, which usually occurs before the formation of the blastocyst. They are usually considered to be totipotent and can therefore differentiate into any kind of cells in the body and can also form a complete organism [9].

ES cells have been derived from a variety of mammalian species over recent years. The first ES cells in mammals were derived from the blastocyst of a mouse in 1981. They had the ability to differentiate into cells of all the three germ layers, were able to form teratomas when injected into immunocompromised mice, and were also karyotypically normal and had the ability to form chimeras [17,18]. An ES cell line has also been successfully established from the Rhesus monkey, which is a nonhuman primate. The cells were shown to satisfy all the characteristics that define pluripotency, such as self-renewal, ability to differentiate into all three germ layers, maintenance of a normal karyotype, and ability to form tumors when injected into immunocompromised mice, apart from showing the presence of the enzyme alkaline phophatase [19]. In the case of humans, the first ES cell line was successfully derived in 1998 from frozen embryos that were obtained from *in vitro* fertilization. They satisfied all the properties of pluripotency and have greatly contributed to stem cell research in recent years [20]. Blastocysts of other species such as rats have also been used to derive ES cells, which were successfully able to contribute to germline transmission and chimera formation [21,22].

11.2.3 Parthenogenetic Embryonic Stem Cells

Parthenogenetic embryonic stem (pES) cells were first described in mice by parthenogenetic activation of haploid embryos using chemicals such as ethanol [23]. Parthenogenesis is a process usually found in lower organisms to generate a live organism directly from an oocyte without activation by a sperm. The mouse embryos

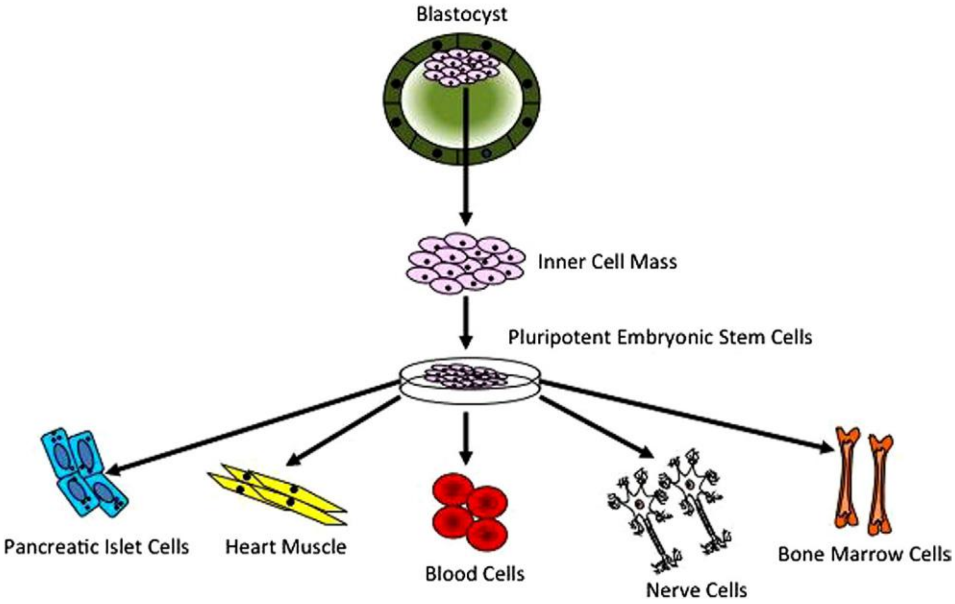

FIGURE 11.1 **Embryonic Stem (ES) Cells.** ES cells are derived from the inner cell mass of the blastocyst. When cultured under suitable conditions, they can be differentiated into cells of the three germ layers: mesoderm, endoderm, and ectoderm. Heart muscle, bone marrow, and blood cells represent the mesoderm; the pancreatic islet cells represent the endoderm; and the nerve cells represent the ectoderm.

generated through this process can only survive upto the blastocyst stage [24]. Parthenogenetic embryonic stem cell lines have been successfully derived from human blastocysts [25] in addition to non-human primates and mice. They behave like ES cells when cultured under appropriate conditions and are pluripotent, apart from contributing to chimera formation [23,26,27].

11.2.4 Germline-Derived Pluripotent Stem Cells

Germline-derived pluripotent stem (gPS) cells are usually derived from unipotent spermatogonial stem cells (SSCs) when established as germline stem cells (GSCs). These GSCs, when cultured under ES cell conditions, give rise to pluripotent stem cells, which are called germline-derived pluripotent stem (gPS) cells [28,29]. Recent studies reported the derivation of GSCs from testicular biopsies of 5–7-week-old adult mice. These techniques can eventually be used to obtain GSCs from human testicular biopsies, which will have great therapeutic potential [30,31].

11.2.5 Induced Pluripotent Stem Cells

Induced Pluripotent Stem (iPS) cells were first derived by Yamanaka et al. in 2006 from somatic cells by induction of pluripotency—a technology that has revolutionized stem cell research. Yamanaka and colleagues successfully reprogrammed embryonic or adult mouse fibroblasts by introduction of four factors: Oct4, Sox2 (SRY, or sex-determining region Y) box 2, c-Myc, and Klf4, using retroviral vector constructs (Figure 11.2). These cells are similar in all their properties to ES cells. They are pluripotent and have a capacity for self-renewal. They contribute to teratoma formation when injected into immunocompromised mice and contribute to the formation of all three germ layers [32]. Pluripotency can also be induced in adult human fibroblasts by addition of OCT4, SOX2, NANOG, and LIN28. These human iPS cells are similar to human ES cells in their ability to self-renew and become pluripotent [33]. They have also been derived from cells of several other animal species, such as pigs and bovine species, and potentially have great therapeutic value.

Induced pluripotent stem cells are derived by various methods. Reprogramming of somatic cells can be achieved by viral transduction (retroviral (lentiviral) and adenoviral). Retroviruses, including lentiviruses, pose the risk of insertional mutagenesis due to genomic integrations, while adenoviruses exhibit less efficient iPS cell generation and need repeated transductions. Recent studies report the use of Sendai viruses, which can be removed via antibody-mediated negative selection post-reprogramming, and are able to achieve efficient reprogramming [34,35]. Several nonviral methods of gene delivery have also been used for reprogramming, including nucleofection of nonviral polycistronic constructs and later excision of the reprogramming factors using a Lox/Cre system and the use of episomal vectors such as the *piggyback* transposon. These nonintegrating methods are usually less efficient for reprogramming. Indeed, most of the aforementioned methods are unsuitable for therapeutic purposes as they all involve the use of genetic material. For this reason, newer reprogramming

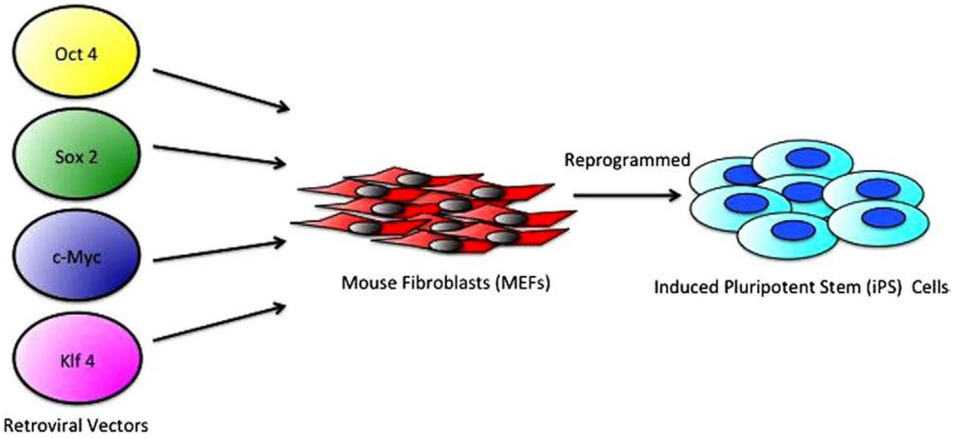

FIGURE 11.2 **Reprogramming of Mouse Embryonic Fibroblasts (MEFs).** The fibroblasts were successfully reprogrammed to pluripotency by overexpression of four factors—Oct4, Sox2, c-Myc, and Nanog—using retroviral vector constructs. The derived cells are similar to ES cells in all of their characteristics and are referred to as induced pluripotent stem (iPS) cells.

strategies that involve the use of mRNAs for delivery of reprogramming factors for iPS cell generation have also been described [34].

11.3 STEM CELL CULTURE METHODS

Cell culture methods are important for the physiological, pharmacological, and biological assessment of stem cells at tissue and molecular levels. Stem cells are usually cultured at 37 °C in the incubator with 5% CO_2 and 95% O_2. The composition of cell culture medium is important for maintenance of stem cells in an undifferentiated state. One of the most commonly used components in stem cell culture is fetal bovine serum (FBS). This, however, has several problems: batch-to-batch variability, the presence of undefined components such as hormones and growth factors (that may cause problems in cell culture) and so forth. Another major concern is the risk of transmission of proteins of animal origin to the patient. Scientists have thus moved to using serum-free culture conditions for making stem cell culture more relevant for clinical use [36].

Various culture systems are available for maintenance and storage of stem cells. For example, to separate MSCs from BM stroma, one of the proposed methods is the addition of 10 ml BM suspension to 20 ml of DMEM (Dulbecco's modified essential medium) containing 10% FBS; this solution can be centrifuged to separate the fat layer, and the cell pellet can then be subjected to density gradient centrifugation for 20 min at 13,000 g using a 70% Percoll solution. The MSC-enriched low fraction can further be cultured in DMEM, supplemented with 10% FBS, in a humidified incubator at 37 °C, and 5% CO_2 and 95% O_2. For further passaging, the cells can be enzymatically dispersed to single cells using 0.25% trypsin and 1 mM EDTA (ethylenediaminetetraacetic acid) and replated in DMEM supplemented with FBS for further maintenance [37]. For cryo-preservation, MSCs can be resuspended in 90% FBS and 10% DMSO (dimethylsulfoxide) by slow freezing and further keeping in liquid nitrogen for long-term storage [38]. For applications in regenerative medicine, MSCs can be can be isolated, stored, and cultured using xeno-free materials like serum-free MesenCult-XF™, TC-protector™, and recombinant trypsin (TrypLESelect™) [39].

For fetal stem cells, culture methods differ based on cell type. For example, cord blood can be collected from the neonatal umbilical cord of normal full-term pregnancies. It can then be sedimented with hydroxyethyl starch for 40–60 min. The mononucleocytes can be isolated by density gradient centrifugation at 400 g for 30 min, further washing in phosphate buffer saline, and resuspension in buffer solution. The CD34+ cells can be further isolated by positive selection using commercially available immunomagnetic separation systems. These isolated cells can be further counted and cultured in Iscove's Modified Dulbecco's Medium (IMDM) supplemented with 10% FBS [40]. For separation of MSCs from umbilical cord blood, the umbilical cord can be rinsed with phosphate buffer saline, disinfected in 75% ethanol, and further minced and digested. The cells can then be cultured in DMEM/F-12 medium supplemented with 10% FBS and 10 ng/ml epidermal growth factor (EGF), and passaged with trypsin. For cryo-preservation, the cells can be resuspended in the usual cryo-preservant solution, which consists of 90% FBS and 10% DMSO [41].

In the case of ES cells, several methods are available for maintenance, culture, and cryo-preservation. Those used for ES cell culture can usually be applied to the culture of iPS cells as well. Originally, human ES cells were derived and maintained in basal medium, which could be supplemented with fetal calf serum and grown on mouse embryonic fibroblast feeder layer (MEF). However, many factors in the serum are undefined and the quality of serum may vary across batches during production. Apart from this, the use of animal components in culture medium can pose a barrier for potential use of these cells for clinical applications.

To overcome these problems, researchers have developed more defined medium conditions for stem cell culture and maintenance. These conditions include hESF9 (consisting of basal medium supplemented with FGF-2 (fibroblast growth factor 2) and heparin sulfate), mTeSR1™, and STEMPRO™, which are commercially available and utilize several chemicals and growth factors to facilitate signaling in the promotion of human ES cell growth. The media are often supplemented with several components such as FGF, transferrin, albumin, cholesterol, and lipid mixtures [42]. ES cells can be passaged enzymatically, such as with dispase, accutase, collagenase, and trypsin, or mechanically, for example, STEMPRO® EZPassage™ disposable stem cell passaging tool, Life Technologies). Human ES cells are mostly frozen and thawed by the usual slow freezing and rapid thawing and subsequent addition of the ROCK inhibitor (Y-27632), which significantly improves recovery of the cryo-preserved cells [43]. The cells can be frozen in 60% KOSR (knockout serum replacement), 20% DMSO, and 20% DMEM in liquid nitrogen.

For parthenogenetic ES cells, the isolated ICMs can be cultured on mitomycin-C–treated mouse embryonic fibroblast cells (MEFs) for about 5–9 days; primary ES cell colonies can then be dissociated mechanically and cultured in human ES cell culture medium consisting of 80% knockout-DMEM, 20% serum-replacement, 1 mM glutamine, 1% nonessential amino acid, 0.1 mM 2-mercaptoethanal, 50 UI/ml penicillin, and 50 UI/ml streptomycin [25].

Human germ cells can be cultivated in gelatin-coated dishes in DMEM with high glucose, supplemented with 15% knockout serum replacement, 2 mM L-glutamine, 0.1 μM β-mercaptoethanol, 100 × nonessential amino acids, 1 × penicillin-streptomycin, 10 ng/ml bFGF (basic fibroblast growth factor), and 0.12 ng/ml TGF-β (transforming growth factor-β). These conditions lead to the formation of small ES cell-like colonies after four days of culture that are pluripotent [44]. The pES, gPS, and iPS cells can be cryo-preserved in ways similar to human ES cells.

11.4 MOLECULAR SIGNATURES OF STEM CELLS

As previously mentioned, stem cells are usually defined as cells that can both self-renew and differentiate into cells of various lineages. In the case of ES cells, the range of lineage options is large compared to other stem cell types such as hematopoietic stem cells, which are lineage restricted and can give rise only to blood cells. For this reason, several different stem cells types have certain shared properties as well as features that distinguish them from one another. It is therefore important to know how various cell fate decisions are made and how lineage commitment in stem cells is regulated. In the case of pluripotent stem cells such as ES cells, histone modifications, polycomb group (PcG) protein-binding patterns, and chromatin accessibility are important features that support pluripotency [45].

11.4.1 Epigenetic Modifications of Stem Cells

ES cells are generally derived from the ICM of pre-implantation blastocysts. These embryos are only transiently pluripotent, and pluripotency is reinstated later on by cells of the primordial germ layer. The primordial germ layer can also be used to generate other types of pluripotent stem cells such as embryonic germ (EG) cells as well as spermatogonial stem cells (SSCs) in adult males. When cultured pluripotent cells are reintroduced into a blastocyst, they give rise to chimeric animals whose adult tissues consist of stem cell–derived progeny. On the other hand, when ES or EG cells are injected into adults, they give rise to tumors known as teratocarcinomas, which consist of cells of all three germ layers. Also, ES and EG cells are capable of reprogramming somatic cells to enable them to re-express markers of their earlier embryonic stages. This requires that the expression of tissue-specific genes be switched off, whereas the expression of pluripotency-related genes such as Oct4 and Nanog must be switched on [45].

Cells of the early embryo have the ability to differentiate into all different cell types and are pluripotent. However, to differentiate into cells of other lineages, ES cells need to lose their potency, which is achieved by stable changes in their genome [46]. It is known that several heterochromatin and euchromatin structures, together with distinct DNA methylation and histone modification patterns, control gene activity and regulate chromatin state and gene expression. There are common epigenetic characteristic among different ES cell lines. Several mechanisms, termed epigenetic mechanisms, exist for regulating gene expression without changes in DNA sequences. The epigenetic information on a large number of genes in stem cells enables understanding pluripotency and mechanisms of genomic imprinting. It also helps in predicting the inclination of some ES cell lines to differentiate more readily than others. Thus, epigenetic signatures can serve as biomarkers for monitoring differentiation, self-renewal, and stem cell development [47]. These mechanisms are classified loosely into three categories: DNA methylation, histone modification, and gene regulation by small interfering RNAs [45].

11.4.1.1 DNA methylation

DNA methylation is a type of DNA modification during which a methyl group is added to the 5′ position of a cytosine base [48]. The process inhibits transcription mainly by two mechanisms: preventing the binding of the transcription factors to the DNA, or interacting with methyl CpG-binding proteins, which recruit histone-modifying and chromatin-remodeling factors. Methylation requires methyltransferases—for instance, DNMT1, which specifically recognizes the semimethylated DNA and goes on to methylate it. On the other hand, DNMT3A and DNMT3B can perform full demethylation [45,46]. DNA methylation and demethylation pathways are important for inducing differentiation in ES cells as well as for achieving pluripotency during somatic cell reprogramming, thus making it important for lineage specification as well as ES cell self-renewal [46,49].

DNA methylation involves the activation of two pathways. One, the AID (activation-induced cytidine deaminase) pathway has been speculated by some researchers to be involved in the demethylation of Oct-4 and Nanog promoters, which are master regulators of pluripotency. The second pathway enables the oxidation of 5-mC (5-methylcytosine) to 5-hmC (5-hydroxy-methylcytosine), 5-fC (5-formylcytosine), and 5-caC (5-carboxylcytosine) by TET (ten-eleven translocation) enzymes by base-excision repair. During somatic reprogramming, demethylation of pluripotency gene promoters can hinder the formation of fully reprogrammed iPS cells [46]. DNA methylation can be identified using several techniques. Most methods suitable for targeted as well as large-scale analysis use bisulphite treatment, which converts unmethylated cytosines to uracils with the methylated cytosine residues remaining unchanged. Bisulphite sequencing enables us to analyze DNA methylation at base-pair resolution. For genome-wide analysis, next-generation sequencing platforms can be used [48].

11.4.1.2 Histone Modifications

Histone molecules are made up of several amino acid residues; the N-terminal amino acids undergo various post-transcriptional modifications such as methylation, acetylation, phosphorylation, ubiquitination, sumoylation, citrullination, and ADP ribosylation. Histone modifications are associated with active as well as inactive chromatin sites. They are also associated with cellular processes such as mitosis, spermatogenesis, and DNA repair. In the case of certain modifications, specific proteins are recruited whereas in others the nucleosome structure is made more accessible to transcription factors through acetylation of residues. Thus histone modifications involve several synergistic as well as antagonistic interactions for the purpose of post-translational regulation [45].

Methylation of Lys27 on histone 3 (H3K27) is a major repressive histone modification and a hallmark of facultative heterochromatin. H3K27 methylation is catalyzed by enhancer of zeste homolog 2 (EZH2), which is part of the polycomb repressive complex 2 (PRC2). In embryonic stem (ES) cells, H3K27me3 is found at promoters of many important genes that regulate development. The mechanism of H3K27me3-mediated repression involves both PRC1 and PRC2. PRC1 acts via the H3K27me3 enzyme and catalyzes monoubiquitylation at Lys119 of H2A. This leads to activation of RNA polymerase II and represses the promoters. PRC1 also facilitates the compaction of chromatin, which is marked by H3K27me3, through a mechanism that is not dependent on its enzymatic activity. H3K27me3 also provides a mechanism to maintain and propagate H3K27me3-marked domains via PRC2. Loss of the repressive histone marks facilitates spontaneous ES cell differentiation. Thus, epigenetic marks prevent premature lineage commitment by silencing genes involved in differentiation.

However, the loss of PCR1 or PCR2 does not affect cell pluripotency [46]. Thus, H3K27me3 and H3K4me3 play a role in developmental gene expression. Loss of H3K27me3 may result in the deactivation of developmental genes that are normally not expressed in pluripotent cells. On the other hand, during lineage specification, the loss of H3K27me3 might result in both the deactivation of developmental control genes and misexpression of either pluripotency genes or other lineage genes. Loss of H3K4me3, on the other hand, may result in a less efficient induction of gene expression during differentiation, or it may result in loss or stochastic activation of gene expression [50]. H3 and H4 histones also undergo acetylation with the help of histone acetyltransferases, whereas deacetylation of histones is achieved by the action of HDAC (histone deacetylase) enzymes. Acetylation and deacetylation are both essential for proper ES cell differentiation as well as for maintenance of adult stem cell function. For example, the inhibition of HDACs prevents the differentiation of ES cells and is important for maintenance of their self-renewal [51].

Histone modifications can be analyzed by chromatin immunoprecipitation (ChIP) using antibodies that specifically recognize the histone tail modification of interest. Downstream methods for identifying exactly which DNA sequences are bound by histones with these modifications include targeted approaches such as quantitative real-time PCR (qPCR) and Sanger sequencing. High-throughput approaches to identify genome histone modifications include ChIP followed by microarray (ChIP-chip) analysis of predetermined regions (such as promoters) or ChIP followed by next-generation sequencing (ChIP-seq) for an unbiased analysis [48].

11.4.1.3 Small Interfering RNAs

Small interfering RNAs (siRNAs) are usually small antisense RNAs, approximately 20–25 nucleotides in length. They are generated from double-stranded RNAs and play a major role in RNA interference pathways by post-transcriptional regulation of gene expression [45]. These regulators of self-renewal in stem cells are part of a complex and interconnected transcriptional network. For this reason, the loss of function of one regulator can, in some cases, can be compensated for by adjusting the expression levels of other network components. Libraries can be developed for screening of siRNAs on a genome-wide scale [52].

11.4.2 Chromatin Modifications of Stem Cells

Chromatin refers to DNA and the proteins associated with it. The basic subunit of chromatin is the nucleosome, an octamer of four core histone proteins (two copies each of H2A, H2B, H3, and H4), around which ~147 base pairs of DNA are wrapped. Chromatin structure can be altered by histone modifications as well as by DNA methylation, which changes the DNA's density and accessibility, thereby modulating the transcriptional potential of the underlying DNA sequence. Histone variations and modifications can affect transcription either *in cis* (by sterically hindering DNA–protein interactions, by changing the charge of the chromatin, or by changing the stability of the nucleosome) or *in trans* (by creating binding platforms for downstream effectors).

Chromatin can also be remodeled and compacted by ATP-dependent chromatin remodelers recruited to specific locations in the genome by modified histones or by proteins with sequence specificity. Long-range interactions can also affect higher-order chromatin structure and transcription by bridging distant genome sites [50]. In ES cells, most genes involved in differentiation are regulated by chromatin-related mechanisms rather than DNA methylation [46]. Chromatin of undifferentiated ES cells is generally loose and less compact compared to differentiated cells, which makes the undifferentiated cells more available for transcription. It has also been shown that most of the transcription factors not expressed by stem cells, but essential for later developmental stages, replicate early in ES cells. Therefore, several lineage-inappropriate genes undergo changes in their chromatin structure and also switch to late replication, when ES cells are induced to differentiate. Gene promoters, which are highly conserved in ES cells, show a bivalent chromatin structure in which both active and repressive chromatin is closely placed. During differentiation, the bivalent chromatin profiles are generally lost and the tissue-specific genes undergo transcriptional activation, which further leads to silencing of the loci associated with alternative developmental pathways [45].

Apart from ES cells, the presence of bivalent chromatin structures is also seen in multipotent adult hematopoietic stem and progenitor cells, as well as neuronal progenitors. Chromatin-modifying complexes such as multiprotein repressive polycomb group (PcG) and activating Trithorax (TrxG) have long been known to regulate lineage specification during embryonic development [51].

11.4.2.1 Polycomb Group Protein Complexes

Polycomb group (PcG) proteins are also known to play a role in maintaining the inactive state of some developing embryos. PcG targets encode several transcription factors that are usually inactive in pluripotent cells but activated upon differentiation. PcG proteins may repress transcription in ES cells through a silencing mechanism that involves the formation of a complex chromatin structure. They may also alter the DNA topology by binding to DNA or to RNA. They are possibly recruited to specific sites in ES cells through stem cell-specific DNA binding factors. In these ways, PcG proteins play an important role in maintaining pluripotency [45]. In order to do so, they repress genes that regulate developmental pathways in such a way that the repression can be maintained epigenetically through cell division. Thus, they maintain the silent state of homeotic gene expression during embryonic development.

PcG proteins are composed of three distinct complexes: PRC1, PRC2, and PhoRC. PRC2 plays a role in the stabilization of repressive chromatin structures with the help of chromatin modifiers such as enhancer of zeste (EZH2), embryonic ectoderm development protein (EED), and suppressor of zeste 12 (SUZ12). All of these belong to the histone methyltransferases group and are responsible for depositing H3K27me2 and H3K27me3 marks onto chromatin. PCR2 is therefore a component of epigenetic memory, which is important for ES cell maintenance. PCR1, on the other hand, is useful in establishing a high-order chromatin structure. Through the activity of the E3 ligase enzyme, PCR1 is able to compact chromatin. Generally, PcG proteins can directly control DNA methylation and can act as connectors between key epigenetic events [51].

11.4.2.2 Trithorax-Group Protein Complexes

Trithorax-(TrxG-) group protein complexes mediate deposition of the histone post-transcriptional modifications responsible for active transcription [51]. They usually antagonize the function of PcG protein complexes, restricting their action to defined tissue-specific and development-specific sets of genes and excluding target genes from repression by PcG genes.

The TrxG protein complex mainly comprises three sets of proteins: the arabidopsis Trx homolog ATX1, the SAND-domain DNA binding protein ULTRAPETALA1 (ULT1), and the chromatin-remodeling protein PICKLE (PKL). ATX1 plays an important role in trimethylation of histone H3 at lysine 4 (H3Kme3). This modification is generally associated with regions that are transcriptionally active. It also regulates PcG target genes such as AGAMOUS (AG) and is involved in gene activation. SAND domains can bind to DNA and are involved in chromatin-associated transcriptional regulation. ULT1, on the other hand, is essential for full expression of AG. PKL is required for maintaining the transcriptional activity of target genes. The final outcome of all transcriptional activity at any given target gene is the result of the balance between the PcG and TxrG proteins together [53].

11.4.3 Alteration of Gene Expression in Stem Cells

Stem cells need to maintain normal expression of their genes, as alterations in gene expression can have a profound effect on cellular states and lead to pathological consequences. Stem cells give rise to progenitors, which are essential for maintenance of healthy organs. This is essential in case other cells in the organs are damaged or lost because of normal wear and tear or disease. During the process of aging, all organs lose cells [54]. The imprinting of maternal and paternal genetic components occurs very early during development. This involves the use of several epigenetic mechanisms. Noncompatible imprinting may lead to abortion or diseases such as malformation and cancer [54,55].

11.4.4 Genomic Imprinting in Stem Cells

Genomic imprinting is an epigenetic process that results in the preferential expression of monoalleles specific to the parent of origin. Most of the imprinted genes identified so far are physically linked in clusters and coordinate regulation. These clusters are very large and are highly conserved between mice and humans. Their structure is highly complex given that the same cluster usually comprises nonimprinted as well as maternally and paternally expressed genes. Imprinting centers (ICs) are the main cluster regions, which regulate the allele-specific expression of many genes [56–60].

11.5 EPIGENOMICS OF STEM CELLS

Epigenomics is defined as a genome-wide study of chromatin regulatory variation. This may include the study of histone post-transcriptional modifications, DNA methylation, nucleosome positioning, and long-range chromosomal interactions. Several methods are used to investigate the forms of this variation. These include chromatin immunoprecipitation (ChiP) for studying local histone post-transcriptional modifications at specific loci. For the analysis of DNA methylation patterns, bisulfite sequencing (BS-seq), restriction enzyme, and affinity approaches can be used. Similarly, genomic regions with low nucleosomal content can be identified by DNAse I hypersensitivity assays, whereas long-range chromosomal interactions can be identified by chromosomal conformation capture (3C) [61].

Recent breakthroughs in next-generation sequencing have allowed rapid adaptation and expansion of existing technologies for genome-wide analyses with better resolution and coverage. These methodologies include MethylC sequencing (MethylC-seq), which can be used for large-scale analysis of DNA methylation at single-nucleotide resolution. With the help of these modern techniques, chromatin signatures that characterize different classes of regulatory elements, such as promoters, enhancers, insulators, and long noncoding RNAs, can be unraveled.

ES cells can thus be used robustly *in vitro* to investigate the molecular and epigenetic basis for pluripotency and embryonic development. The chromatin of pluripotent cells has several unique features, including increased mobility of many structural proteins such as histones and heterochromatin protein 1. It also shares many fundamental properties with the chromatin of somatic cells. However, nuclear organization in ES cells is different from that in somatic cells and they have a less compact chromatin structure. The unique epigenome of ES cells promotes their epigenetic plasticity.

11.5.1 Epigenetic Variation among Pluripotent Stem Cells

Recent studies by Takahashi and Yamanaka reported the reprogramming of fibroblasts with forced introduction, via retroviral vectors, of the transcription factors Oct4, Sox2, Klf4, and c-Myc to generate iPS cells [32]. Induced iPS cells are successfully derived from a variety of somatic cells; they are phenotypically and molecularly similar to ES cells in many ways, including their gene expression patterns and their unique properties of pluripotency and self-renewal. However, the full extent of this similarity is still not clear. As with ES cells, tetraploid embryo complementation of most iPS cells can give rise to all tissues of the embryo proper. However, some iPS cell lines are unable to fulfill the criteria of pluripotency. Epigenetic studies comparing DNA methylation and histone modification patterns in ES and iPS cells may help unravel the differences in the behavior of these two cell types [61].

Most comparisons show that the majority of ES cell features are re-established during iPS cell reprogramming. However, subtle differences are observed in the DNA methylation and gene expression patterns between iPS and ES cells. They fall into three main categories: (1) experimental variability in cell line derivation and culture, (2) genetic variation among cell lines, and (3) systematic differences representing hotspots of aberrant epigenomic reprogramming [61].

The first category may not necessarily represent meaningful biological distinctions between the two cell types, but it can nevertheless be important when the quality or differentiation potential of the individual lines needs to be assessed. The second category is mainly a result of genetic variation between the different sources of the human cells or embryos from which these iPS cells or ES cells are derived.

Genetic variation is mainly due to the differences within cell lines with respect to DNA and histone modification patterns. This calls for using stringent statistical analyses when comparisons between ES and iPS cells are made [61].

Recent studies of specific chromatin features in lymphoblastoid cells indicate that human genetic variation has significant impact on epigenetic landscapes. They show that, irrespective of whether these cells are isolated from related or unrelated subjects, they exhibit individual as well as allele-specific, heritable differences in chromatin signatures. These differences can be largely attributed to underlying genetic variants [61–63]. Also, the differences in the epigenomes of ES and iPS cells may arise because of many other factors, such as maintenance of epigenetic memory (somatic memory) during reprogramming in iPS cells or selective pressure during reprogramming. However, understanding epigenetic differences between human ES and iPS cell lines is essential for harnessing their potential in regenerative medicine [61].

It has been observed that, in several defined models of mouse reprogramming, differences in gene expression and differentiation potential that are specific to cell type of origin exist, especially in early-passage iPS cells. Thus, the hypothesis that an epigenetic memory of previous fate persists in these cells is reinstated. This epigenetic memory is mainly due to the presence of residual somatic DNA methylation in iPS cells. Most of it is retained within regions in proximity to CpG islands. Because of this incomplete loss of somatic methylation, iPS cells are sometimes predisposed to differentiation into fates related to the cell type of origin and thus differentiation into other lineages can be restricted in them. However, continuous passaging, serial reprogramming, and further treatment with small molecules, which act as histone deacetylase inhibitors or as inhibitors of DNA methyltransferase activity, can erase this memory. Studies show that the remnants of somatic DNA methylation are transient and can be erased from iPS cells through replication and cell division [61].

A recent study also demonstrated that in spite of similar DNA methylation landscapes in iPS and ES cells, the presence of hundreds of differentially methylated regions (DMRs) can be observed. Moreover, only a small fraction of DMRs seem to fail in erasing somatic DNA methylation, but the vast majority of the differences in DNA methylation patterns mainly correspond either to hypomethylation (defects in the methylation of genomic regions marked in ES cells) or to the appearance of iPS cell-specific methylation patterns, which are generally not present in ES cells or in the somatic cell type of origin. These DMRs are mostly resistant to passaging, especially in late-passage iPS cells. This study was performed using a limited number of iPS and ES cell lines, genetic and experimental variation among individual lines may yet be found to be a big contributor to the reported DMRs. However, iPS cells of different genetic background and cell type of origin do share nonstochastic epigenomic hotspots that pertain to reprogramming [61,64].

Apart from erasing somatic epigenetic marks, it is essential that ES cell-like epigenomic features be reestablished during reprogramming. In iPS cells, in the areas surrounding the centromeres and telomeres, reduced DNA methylation may sometimes be observed. This biased reduction, which is observed in subcentromeric and subtelomeric regions, may be attributed to the blocks of H3K9me3 in these regions. Their surrounding aberrant DNA methylation patterns may play a role in rendering the telomeric and centromeric regions more resistant to epigenetic changes. Recent studies have observed the presence of histone variant H3.3 in the subtelomeric and subcentromeric regions of mouse ES cells and mouse embryo. This histone is generally involved in transcription-associated and replication-independent histone deposition. Apart from this, it is known that histone H3.3 is important in the maintenance of transcriptional memory during reprogramming by somatic cell nuclear transfer. For this reason, it can be speculated that a similar mechanism may contribute to the resistance of reprogramming in the regions surrounding the telomere and centromere in iPS cells [61].

All pluripotent cell types constantly anticipate alternative developmental fates and thus show the existence of poised promoters and enhancers in their epigenome. It has been clearly demonstrated that in iPS cell promoter regions, bivalent domains are reestablished. However, more studies need to be performed in order to assess the extent to which the chromatin signatures associated with these poised developmental enhancers are recapitulated in iPS cells. The existence of developmental enhancers, which are associated with genes that are inactive in ES cells but active in post-implantation steps of embryogenesis, suggests that proper enhancer reassembly to a ES cell-like state is essential for determining the differentiation potential of iPS cells. If the developmental enhancers are not properly epigenetically marked, an impaired differentiation of the iPS cells may result, although the transcriptional or promoter modification level in the undifferentiated state may remain unaffected. It is therefore important that the epigenomic profiling of enhancers and promoters be taken into consideration when determining the quality and differentiation potential of iPS cell lines [61].

11.5.2 Importance of Epigenomics in Pluripotent Stem Cells for Regenerative Medicine

Epigenomics can be useful in the study of human development and disease. Apart from this, it can be useful for translation of stem cell technologies into clinical applications. With the help of epigenomic profiling, annotation of functional genomic elements can be achieved in a genome-wide and cell type–specific manner. The distinct chromatin signatures obtained by epigenomics can help identify and distinguish between active and poised promoters and identify insulator elements and the presence of noncoding RNAs that may be transcribed in a given cell type.

As epigenetic marking of promoters and enhancers determines developmental potential, epigenomic mapping can be a better tool to identify the differentiation potential of iPS cells compared to that of transcriptome profiling. However, it is important to assess the quality of iPS cells and human ES cells before using them in translational applications. For this purpose, appropriate resources need to be developed. For example, although ChIP-seq analysis of chromatin signatures is extremely informative, relying on the quality of antibodies used, it requires the development of renewable, standardized reagents. Also, to assess the significance of epigenomic pattern variation, sufficient numbers of reference epigenomes need to be obtained from human ES and iPS cell lines. These should be representative of genetic variation and have been rigorously tested in a variety of differentiation assays [61].

Because of ethical and practical limitations, very little is known about the regulatory mechanisms that govern early human embryogenesis. However, human ES cell–based differentiation models offer a unique tool for isolation and study of cells that correspond to transient progenitor states arising during human development. Moreover, subsequent epigenomic profiling of human ES cells that have been differentiated *in vitro* along specific lineages can be used to define and identify the functional genomic regulatory space, or "regulatome," of any given cell lineage. This approach can be extremely useful for identification of genome-wide tissue-specific enhancers and silencers, which are highly variable among both different and closely related cell types.

Characterization of cell type–specific regulatomes can be useful for comparative analyses of gene expression profiles. In addition, through bioinformatic analysis of the underlying DNA sequence, they can be used for the prediction and identification of novel master regulators of specific cell fate decisions, which can subsequently serve as candidates in the development of direct trans-differentiation approaches. Moreover, mapping of enhancer profiles provides an enormous resource in the development of reporters for isolation and characterization of rare human cell populations, such as the progenitor cells that mostly arise only transiently during development. Ultimately, this knowledge will be helpful in the refinement of current differentiation protocols and derivation of a better-quality and well-defined population of cells that are safer and more appropriate for replacement therapies. Also, characterization of cell type–specific regulatomes will be useful for understanding noncoding variations in human disease [61].

During the past few years, genome-wide association studies have dramatically identified several new genetic variants associated with some of the most common human disorders, such as various types of cancer, type 2 diabetes, obesity, cardiovascular disease, Crohn's disease, and cleft lip/palate. However, most of these variants occur in the noncoding parts of the human genome, which suggests the existence of a large noncoding component in human phenotypic variation and disease. Several reports have also highlighted the critical role played by genetic aberrations, which occur within individual distal enhancer elements in human pathogenesis. So far, the exact role of regulatory sequence mutation in human disease has not been examined in detail, but, given the rapidly decreasing cost of high-throughput sequencing and multiple disease–oriented, whole-genome sequencing projects that are under way, the coming years will be crucial in allotting functional significance to disease-associated noncoding mutations.

Nevertheless, for this purpose it is important to identify and obtain cell types relevant to disease, as well as to characterize their specific regulatomes. In the future, the combination of pluripotent cell differentiation models and epigenomic profiling will be an important tool for uncovering the role of noncoding mutations in human disease. For example, if the disease of interest affects a particular cell type that can be derived *in vitro* from human ES cells, characterization of its reference regulatome may reduce the vast genomic regions implicated in a particular disease into a much smaller regulatory space that can be more effectively examined for recurrent variants associated with that disease.

The function of regulatory variants can be further studied using *in vitro* and *in vivo* iPS cell–based disease remodeling strategies. For example, disease-relevant cell types obtained from patient-derived and healthy donor–derived iPS cells can be used to study the effects of the disease genotype on regulatomes specific to a certain cell type. Moreover, given that most regulatory variants are not likely to be heterozygous in patients, loss or gain of chromatin features associated with those variants (such as p300 binding, histone modifications, and nucleosome occupancy) can be assayed independently for each allele within the same iPS cell line. Indeed, researchers have recently developed allele-specific sequencing assays, the results of which can be compared with allele-specific RNA-sequencing transcriptome analyses from the same cells. Such studies may provide valuable insights into the effects of disease-associated regulatory alleles on the transcription of genes located in relative proximity to the chromosomes [61].

Analysis of human ES cell and iPS cell chromatin landscapes have helped to provide important insights into the molecular basis of pluripotency, reprogramming, and early human development. Next-generation sequencing technologies such as ChiP and MethylC have been important in the study of the pluripotent cell epigenome. Several chromatin features, such as bivalent promoters, poised enhancers, and pervasive non-CG methylation are known to be more abundant in human ES cells as when compared with differentiated cell types. It is essential that future studies dissect the molecular function of these epigenomic attributes and their relevance to human ES cell biology.

Epigenomic tools have been widely used in the evaluation of iPS cell identity. In general, the epigenomes of the iPS cell lines are known to be very similar to those of human ES cell lines, although recent reports suggest that some differences in DNA methylation patterns are observed between the two. It will be important to understand the origins of these differences (that is, somatic memory, experimental variability, and genetic variation) and their impact on iPS cell differentiation potential, as well as to determine their clinical applications.

It is important that additional epigenetic features other than DNA methylation be thoroughly compared, including proper reestablishment of poised enhancer patterns. A more complete picture of the epigenomes of ES and iPS cells will be helpful for useful insight into the developmental decisions in humans, which will not only help to improve our understanding of human development but also facilitate the establishment of robust *in vitro* differentiation protocols for clinical applications. These advancements will in turn allow for generation of replacement cells for cellular transplantation and for development of appropriate *in vitro* disease remodeling strategies. With the help of *in vitro* disease models, epigenomic profiling can easily be achieved; this will promote understanding of the genetic basis of complex human disorders, especially where most of the causative variants are predicted to occur within the vast noncoding fraction of the human genome [61].

11.6 PHARMACOGENOMICS OF STEM CELLS

Cell-based assays are used to detect a probable genetic predisposition to toxicity during early drug development. Fewer reliable and stable sources of diverse cell populations are available for the study of genomics-based drug toxicity, but human pluripotent stem cells can be easily used for the development of toxicity assays for drug screening. Not only do these cells have a unique ability of self-renewal, but they are also genetically more stable than transformed cells and can differentiate into virtually any cell type in the body. Human embryonic stem cells and human induced pluripotent stem cells have similar differentiation potential, and their ability to differentiate into different cell types that are clinically relevant for disease remodeling, drug screening, and cell replacement therapy, has been studied extensively [65].

Many protocols have been published for directed differentiation of these cells into various cell types, such as cardiomyocytes, neurons and glia, pancreatic cells, and hepatocytes. However, these differentiated cells may not necessarily express all of the characteristics of mature adult cells. The liver plays a major role in drug metabolism *in vivo*. For this reason, development of *in vitro* protocols for differentiation of pluripotent stem cells into functional hepatocytes are of prime importance in toxicity assessment [65]. Hepatocytes have been generated by several researchers *in vitro*, using stepwise differentiation protocols based on sequential addition of several cytokines and growth factors. These protocols are based on the *in vivo* embryonic development of the mammalian liver, which includes initial differentiation into definitive endoderm, followed by hepatocyte specification and finally hepatocyte maturation. The purity of the cultures is further monitored at each stage of differentiation by checking for marker expression; markers that are typically expressed at that stage.

For purification and enrichment of cultures, several techniques are employed, including fluorescence-activated cell sorting (FACS) using antibodies for detection of surface markers (e.g., asialoglycoprotein receptor 1 and E-cadherin) and reporter assays for determining albumin or anti-trypsin expression. These techniques generate cell populations similar to hepatocytes. In this respect, they show an ability to store glycogen and to express albumin and cytochrome P450s, thereby also exhibiting functional similarity to hepatocytes [65–76].

Hepatocytes have a unique ability to metabolize drugs with the help of cytochrome P450 enzymes. Obtained from pluripotent stem cells, they show expression of these enzymes at levels lower than those of adult hepatocytes or adult liver. This can be a major setback in their use for toxicity assays and drug development [65].

11.6.1 Generation of Ethnically Diverse Pluripotent Stem Cells for Pharmacogenomic Studies

The derivation of functional hepatocytes able to metabolize drugs may help in the development of cell toxicity assays. Such assays can be useful for testing the pharmacogenomic effects of drugs before they are released in the market. Every human ES and iPS cell line has a unique genome, which promotes the possibility of obtaining a collection of pluripotent stem cells that represent the ethnic diversity of the population targeted by a particular drug. However, this is not the case in reality. Recent studies have shown that most human ES cells being used are from either European or East Asian ancestry and thus lack ethnic diversity. Ethical concerns as well as the technical expertise required for ES cell generation further contributes to their lack of diversity [65,77,78].

Problems surrounding the use of human ES cells can be easily overcome by generating human iPS cells from a variety of sources. Different human iPS cell types can be derived from many living individuals, allowing for the possibility of preselection of chosen genotypes to create collections of cell lines that serve a specific purpose. These may include cell lines that represent a specific genetic disease for research purposes. So far there have been no collections of human iPS cells that specifically represent variants of drug metabolism enzymes. However, there are plans for a collection of HLA variants, which may be useful in cell generation and, in the future, suitable for cell therapy in regenerative medicine [65].

11.6.2 Creating Stem Cell Banks for Pharmacogenomic Studies

There are challenges to be overcome in establishing the routine use of human iPS cells in pharmacogenomics studies. The first is the investment required for the collection of somatic cells from diverse individuals. Further on, infrastructural investments will need to be made to assess the quality of the collected cells. Assessment can be carried out using genomic analyses, which may help in cell characterization. Still, this challenge needs to be addressed before any cells are used in drug screening for pharmaceutical development [65].

Another challenge that needs to be overcome is developing human iPS cell lines which can be used for culture and differentiation to obtain the huge numbers of cells needed for toxicology and drug screening studies in large-scale analyses. Also, it is important that cells obtained from human iPS cells are able to represent the adult and fully functional form of the desired cell type in order to be considered for use in cell therapy and drug-screening strategies [65].

Genome editing in human stem cells can be successfully achieved with the help of meganucleases, zinc-finger nucleases, adeno-associated viruses, and transcription activator-like effector nucleases [79–84]. These allow efficient introduction of a variety of genetic alterations, ranging from single-nucleotide modifications to whole-gene addition or deletion, all with a high degree of target specificity into iPS cell lines. A strong rationale for using genome-edited cell models for phenotypic studies is that, by assessing the effect of a DNA variant on an isogenic background, potential confounders will be minimized [84]. This has the potential, in the near future, of replacing genetically modified mice. Genome editing will make it possible to go beyond disease modeling towards the discovery of therapeutics. For example, genome-editing tools should make it straightforward to insert reporters into the genomic loci of interest, allowing RNA-interference screens or small-molecule screens to identify genes and probes that have the desired functional effect [79–84].

11.6.3 Use of Stem Cells for Toxicogenomic Studies

The use of stem cells to assess the risk of toxic agent exposure to human beings can lead to new developments in toxicogenomics. The effect of several toxic reagents can be tested *in vitro* via pluripotent cell–based assay—for example, studies can be carried out on the epigenetic mechanisms that cause teratogenic effects in the embryo due to treatment with thalidomide, an otherwise non-mutagenic and non-cytotoxic compound. The effects of other non-mutagenic but tumor-promoting epigenetic toxicants such as DDT can also be tested *in vitro*. The role of stem cells in the development and progression of cancer can also be well studied [54,85,86].

With the help of embryonic stem cells, studies can be carried out on the effects of mutagens on undifferentiated embryonic cells as well as the differentiated somatic cells derived from them. Moreover, these cells serve as a tool to study the dose-dependent effect of mutagenic compounds. The mutagenic potential of DNA alkylating reagents such as *N*-ethyl-*N*-nitrosourea (ENU) and *N*-methyl-*N*-nitro-*N*-nitrosoguanidine (MNNG), as well as the DNA cross-linking and alkylating substances such as mitomycin C (MMC) can also be investigated on undifferentiated versus differentiated cells. There is a noted difference in the sensitivity to mutagens as well as rates of mutations between undifferentiated stem cells and their differentiated somatic derivatives [54,87].

Cellular responses differ. This is observed in stem cells with different genetic backgrounds and gender, where the genetic background of the test system is important in the interpretation of results. Similarly, cellular responses differ with respect to gender when mouse stromal stem cells are exposed to an extremely low-frequency EMF. For example, in colony-forming unit of fibroblasts (CFU-f) assay, it has been observed that the stromal cells from female mice show a reduction in proliferation while those from male mice do not [54,88,89].

11.7 POTENTIAL OF STEM CELLS

Stem cells can be used in a wide range of applications—particularly in the development and screening of new drugs as well as in future cell replacement therapies. Pluripotent stem cells can therefore serve as an important tool in detailed studies of various diseases. Such studies in turn can be useful in the development of new strategies for treatment of disease (Figure 11.3).

11.7.1 Use of Stem Cells for Disease Modeling

Stem cells offer immense opportunities in unraveling the pathological mechanisms of several human diseases. They can also be used to develop new therapeutic strategies in a preclinical setting. ES cells and the more recently developed iPS cell technology provide an unlimited source of cells unlike primary cell cultures. ES or iPS cell lines can be useful in extrapolating results from animal studies and in potentially overcoming some of the limitations of animal models. Recent studies have successfully shown that iPS

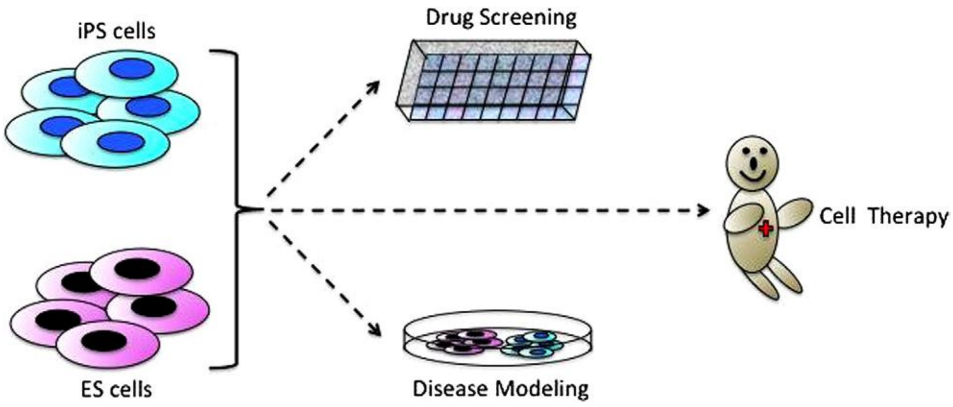

FIGURE 11.3 Potential of Pluripotent Stem Cells. Cells, such as iPS and ES, can be used for screening new drugs and modeling various human disorders *in vitro*; they also have potential in cell replacement therapy when differentiated into the desired cell type.

cells derived from patients may be useful for *in vitro* remodeling of inherited as well as multifactorial human disease. Thus they may in turn enable screening and validation of potential pharmacological compounds [90].

Robust protocols are available for differentiation of pluripotent stem cells into neurons; this has accelerated the development of stem cell–based models for the study of neurological disorders. Recently, iPS cells were derived from the fibroblasts of a child suffering from spinal muscular atrophy (SMA), which is an autosomal recessive genetic disorder caused by mutations in the SMN1 gene. Compared to the control iPS cell lines, the motor neurons derived from the SMA-iPS cell line showed a reduction in the expression of SMN1 protein, smaller size, and poor survival after prolonged culture *in vitro*. Notably, SMA motor neurons also responded to the SMN-inducing compounds, such as valproic acid and tobramycin, by upregulating SMN protein expression level [91]. This may provide a platform for future large-scale drug screening studies.

Recent studies have demonstrated that iPS cells can be used for modeling of diseases such as familial dysautonomia (FD), an autosomal recessive congenital neuropathy caused by a point mutation in the IKBKAP gene [92]. These studies have been successful in reproducing several aspects of the pathogenesis of the disease, including the mis-splicing of the IKBKAP gene and defective neurogenesis, which involve defective motility in FD-iPS cell–derived neural crest precursor cells. Long-term treatment with the drug kinetin seems to improve motility [92]. One study focused on X-linked MeCP2 gene mutations, which are commonly found in patients with the progressive neurodevelopmental disorder known as Rett syndrome. It reported that structural and functional abnormalities in neurons derived from Rett-iPS cells increased as a result of fewer dendritic spines, reduced synaptogenesis, abnormal calcium signaling, and electrophysiological defects [93]. Importantly, the beneficial effects of the previously identified drugs IGF1 and gentamicin in improving neuronal morphology and synaptogenesis [90] were confirmed.

The potential of iPS cells in modeling adult-onset and complex neurodegenerative diseases has been explored. In one study, iPS cell lines derived from fibroblasts in patients suffering from schizophrenia (SCZD) showed a decreased neuronal connectivity compared to healthy controls. In SCZD-iPS cell–derived neurons, the activity was improved by treatment with the antipsychotic drug loxapine [94]. In another study, iPS cells carrying a mutation in the LRRK2 gene, which is commonly associated with Parkinson's disease (PD), were differentiated into dopaminergic neurons and then exposed to stress agents. Compared to control iPS cell–derived dopaminergic neurons, PD-dopaminergic neurons showed an accumulation of a synuclein protein, an increased expression of oxidative stress response genes, and an enhanced sensitivity to neurotoxic reagents [95].

Very recently, iPS cells were derived from fibroblasts of patients with Alzheimer's disease (AD) in which mutations are present in the presenilin genes. Researchers observed that the neurons derived from AD-iPS cells had a higher secretion of amyloid β-42, which is a hallmark feature of familial Alzheimer's [96]. Moreover, these disease-specific iPS cells were responsive to g-secretase inhibitors, demonstrating the feasibility of this system for testing novel compounds for treatment of Alzheimer's [90].

Besides neurological disorders, iPS cell technology may prove useful as a tool for elucidating the molecular basis of cardiovascular and metabolic conditions, as well as for the development of assays for identification and screening of candidate drugs. For example, iPS cell–based modeling of long QT syndrome has been attempted independently by several groups and has demonstrated electrophysiological defects in long QT-iPS cell–derived cardiomyocytes. These defects can be partially restored by pharmacological agents [97–99]. Also, iPS cells derived from patients with LEOPARD syndrome have been shown to differentiate into cardiomyocytes that display hypertrophic features similar to those observed in patients [90,100].

Cell culture conditions for inducing definitive endoderm from pluripotent cells followed by hepatic specification are relatively well established. This has enabled several researchers to reproduce the key pathological events that define liver diseases *in vitro*. iPS cell lines have also been generated from patients suffering from inherited metabolic liver disorders. They have been successfully differentiated into hepatocytes or cells of the liver lineage. An aggregation of misfolded a1-antitrypsin (A1AT-alpha 1 anti-trypsin), for example, was observed in the endoplasmic reticulum of hepatocytes derived from iPS cells of patients with a1-antitrypsin deficiency [101]. Similarly, hepatocytes derived from iPS cells of patients with familial hypercholesterolemia (FH) had impaired LDL receptor–mediated cholesterol uptake, whereas those derived from glycogen storage disease type 1a patient fibroblasts showed accumulation of excessive amounts of lipid and glycogen and produced high levels of lactic acid [101]. As a first step toward an iPS cell–based model of type 1 diabetes, iPS cells were derived from fibroblasts that generated insulin-producing glucose-responsive cells *in vitro*. However, their efficiency was low [102]. Successful application of this model may require improved differentiation protocols as well as incorporation of immune cells isolated from the patient's blood or generated from iPS cells *in vitro* [90].

11.7.2 Use of Stem Cells for Toxicity Modeling

In recent years, immense improvement has been achieved in the development of experimental methods for screening compounds that are developmentally toxic and for elucidating the mechanisms responsible for their toxicity. Instead of animal models and highly laborious *in vivo* tests, we are now equipped with a rich source of human-derived materials, especially from ES and iPS cells. These show great potential in replacing conventional *in vivo* methods and are easily adaptable to a wide range of applications. Researchers are now focusing on completely validating and optimizing ES and iPS protocols that will significantly reduce or eliminate reliance on conventional and complicated *in vivo* protocols [103].

11.7.2.1 Use of Stem Cells in Cardiotoxicity Studies

It is important that the subclinical cardiotoxicity of new chemical entity (NCE) drug candidates is well assessed before their use in clinical applications. The detection of cardiotoxicity is crucial in preclinical stages, as it remains one of the leading causes of drug failure. Accurate and early detection of the effects of NCE drug toxicity is hampered, however, because of insensitive drug screening assays and assays that do not fully recapitulate the complex phenotype and exact effect of fully functional cardiomyocytes *in vivo* [103].

One of the most commonly observed cardiotoxic effects of NCE drugs is delayed repolarization of the ventricular action potential, mainly caused by transmembrane ion flux, which is detected electrophysiologically as a prolonged QT interval. A possible result is life-threatening ventricular tachyarrhythmia [104]. Most current toxicity tests are expensive and labor-intensive; they are encumbered by a high level of inter-experimental variability and by the large number of animals required. Also, the similarity between drug responses observed in animal models and in their human equivalents is not always observable because of huge amounts of interspecies variability.

To overcome these hurdles, mature cardiomyocytes isolated from humans are used as the cellular model for drug safety screening, although they are extremely difficult to harvest because of their limited availability, lower proliferative capacity, and disease state variability, especially when isolated from cadavers. Nevertheless, recent advances have created an unlimited source of cardiomyocytes that can be constantly replenished. Derived from human pluripotent stem cells, they can act as an alternative *in vitro* screening system. Much research is focused on the development of pluripotent stem cell–based cardiac models for testing toxicity. Early studies derived cardiomyocytes from mouse ES cells and hinted at their potential in drug safety screening and toxicology. However, because of interspecies variation, results based on mouse ES cells cannot be directly extrapolated to humans [103].

Several protocols have been developed for deriving cardiomyocytes from human ES and iPS cells. Some make use of spontaneous differentiation in three-dimensional spheroids known as EBs (embryoid bodies) [105]. Others use co-culture methods involving, for example, undifferentiated cells and END2 cells [106,107]. Generally, the number of beating EBs produced ranges from 0 to 70% of the total, and their composition is highly variable. Cardiomyocytes may make up only <25% of the total, with the rest mostly fibroblasts of endodermal lineage. Such huge heterogeneity may be due to differences in stem cell lines, in differentiation protocols, or in culture media, and methods used. Strategies to improve differentiation include the use of small molecules and growth factors. The efficiencies achieved are usually approximately 50%.

Selection can be used to obtain pure populations of cardiomyocytes from differentiating pluripotent stem cells. It can be carried out using manual methods such as dissection of contracting cells and centrifugation. An alternative is negative or positive selection for identified endogenous cardiomyocyte surface markers using fluorescent activated cell sorting. Cells can also be selected using reporter assays or marker genes. With any of these methods, cardiomyocytes with up to 99% purity can be obtained from differentiating pluripotent stem cell cultures [103].

Both of the widely used sources of pluripotent stem cells, iPS and ES cells, have been reported to differentiate into cardiomyocytes that have similar gene expression profiles and electrophysiological properties. Moreover, they are known to respond to cardioactive drugs in a similar way, although in some cases iPS cells may have impaired differentiation potential [108−110]. The differentiation of these cells into beating cardiomyocytes in terms of gene expression has been shown to be similar to the *in vivo* developing heart. Researchers have observed downregulation in the expression of pluripotency markers such as Oct4 and Nanog. They have also observed upregulation of cardiac transcription factors (e.g., NK2 transcription factor–related (NKX2.5) and myocyte enhancer factor 2C (MEFC2C)), as well as genes encoding structural proteins (e.g., myosin-heavy poly- peptide 7 (MYH7) and cardiac ion channels [111–113].

However, there are differences in pluripotent stem cell–derived cardiomyocytes compared to their adult phenotype. Immunofluorescence studies show the presence of cardiac structural proteins such as α-actinin and myosin light chain, but they exhibit relatively disorganized sarcomeric striations with a multi-angular appearance, similar to those of the human fetal cardiac phenotype, compared to adult cardiomyocytes, which have a more rod-shaped morphology and organized sarcomeric striations [106,114,115]. Also, pluripotent stem cell–derived cardiomyocytes lack the developed T tubule system that typically exists in mature cardiomyocytes [115]. Additionally, they behave electrophysiologically like 16-week-old fetal human ventricular cardiomyocytes and have a low resting membrane potential with low intracellular calcium handling [103].

Because pluripotent stem cell–derived cardiomyocytes can be maintained in culture for at least five months, their maturation can be induced if required [115,116]. It has been shown that the number and organization of myofibrils increase with time beyond day 50 of culture. In continuous culture, a high degree of sarcomeric organization may be observed in the differentiated cardiomyocytes with occasional formation of a T tubule system, indicating a phenotype that is compatible with mature cardiomyocytes [115,116]. The discrepancies between pluripotent stem cell–derived cardiomyocytes and their mature phenotypes may be due to secondary factors such as differences in the cell lines used, in the differentiation and culture protocols employed, and in the architecture of the cardiomyocytes being assessed. The relative immaturity of the differentiated cardiomyocytes ultimately may not matter as long as the cellular model is able to predict clinical outcome [103].

Microelectrode arrays (MEAs) and patch clamp techniques have been used to microscopically evaluate the beat alterations and electrophysiological changes, which are caused by several compounds, in pluripotent stem cell–derived cardiomyocytes. The results obtained have been as expected. The drugs evaluated include a variety of pharmacological classes such as adrenoceptor agonists and antagonists, muscarinic receptor agonists, acetylcholine inhibitors, calcium channel inhibitors, hERG potassium channel inhibitors, phosphodiesterase inhibitors, sodium channel inhibitors, and multiple ion channel blockers. Although derived *in vitro*, differentiated cardiomyocytes do show good predictivity of clinically observed cardiotoxicity, which makes them useful tools in drug discovery and safety pharmacology [103,117,118].

A complete assessment of the potential of stem cell–derived cardiomyocytes for use in drug toxicology can be carried out with the help of critical comparisons in sophisticated dose-response studies, using different concentrations of the drugs in patients under treatment. Direct comparisons with currently used *in vitro* and *in vivo* models are also required to demonstrate complete competency. To test the cardiotoxic effects of several known compounds, high- throughput screening platforms may be used for drug screening in 96-well formats using functional assays [103].

iPS cell–derived cardiomyocytes have several advantages over those derived from ES cells. For instance, they can be potentially used in safety pharmacology studies for selection of optimal medications for specific diseases. A recent study reported that an iPS cell–derived cardiomyocyte, carrying a congenital long QT syndrome type 2 mutation, developed early after depolarizations of the clinically used stressor isoprenaline. This effect was reversed by the beta-blocker nadolol, which has been used as therapy. This study concluded that iPS cell–derived cardiomyocytes respond appropriately to clinically relevant pharmacology, proving them to be a valuable *in vitro* model for disease modeling and individualized drug testing. From a drug-screening perspective, it may be possible in the future to generate a library of iPS cell–derived cardiomyocytes that reflect pharmacogenetic variations in the human population [103,119].

iPS cell–derived cardiomyocytes can also be used in unraveling the mechanisms associated with cardiac disorders. For example, in a recent study those from patients with the rare autosomal-dominant LEOPARD syndrome were used to study the pathophysiology of this disease *in vitro*. The obtained cardiomyocytes showed hypertrophy, which is a commonly encountered feature of patients in this group. Through their ability to model these genetically characterized diseases *in vitro*, patient-specific iPS cell–derived cardiomyocytes may also allow a deeper understanding of disease mechanisms and thus help to identify novel drug targets [100,103].

Pluripotent stem cell–derived cardiomyocytes show great potential in the evaluation of drug safety and toxicology studies. They are being increasingly used for disease modeling to understand the pathophysiology of drugs and to potentially identify new therapeutic targets. Though preliminary studies have been successful in drug safety evaluations

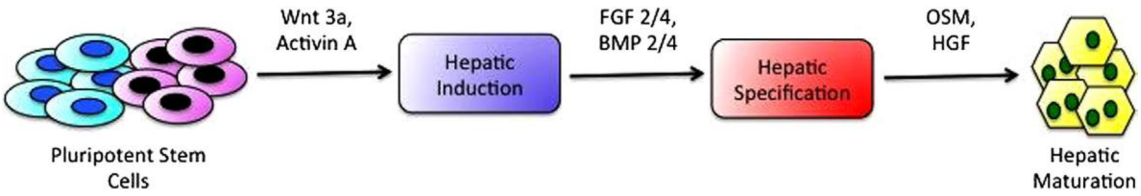

FIGURE 11.4 **Hepatic Differentiation of Pluripotent Stem Cells.** These cells can be differentiated *in vitro* in a stepwise manner by the addition of cytokines—Wnt 3a and Activin A help induce the cells toward hepatic differentiation. The differentiating cells can be specified toward a hepatic lineage by the addition of FGF 2/3 and BMP 2/4. Further maturation into hepatocytes can be achieved by the addition of OSM and HGF.

and high clinical predictions of cardiotoxicity, more studies are needed to confirm these results. Also, some practical issues need to be overcome. Recently reported methods are highly efficient, but newer differentiation and enrichment protocols need to be developed to routinely obtain pure cardiomyocyte populations. Also, these methods should be potentially usable in drug safety and drug toxicology evaluations in robust high-throughput screening formats, as well as scalable. Moreover, a refined cardiomyocyte population should be available for drug safety testing [103].

11.7.2.2 Use of Stem Cells in Hepatotoxicity Studies

Most of the current research in hepatic toxicology focuses on improving existing *in vitro* cellular models to optimize both their reliability in toxicology predictions and their ability to uncover associated metabolic pathways. The liver plays an important role in drug metabolism and excretion; adverse drug reactions (ADRs) are mostly caused by drug-induced liver injury [103,120].

The liver is a highly complex organ comprising several cell types. Usually preclinical drug testing for it is performed on several well-established *in vivo* and *in vitro* models from humans and rodents. However, interspecies differences in liver metabolism exist that make it difficult to extrapolate preclinical data to the clinic. For this reason, many drugs fail in human trials or are removed from the market because of hepatotoxicity. Efforts are being made to develop new models in order to optimize new compounds [103].

Since ES cells have been available for quite some time, a great deal of work has been done to obtain hepatocyte-like cells from them. Current protocols for the derivation of hepatocytes from ES cells usually focus on mimicking the pathways involved during *in vivo* liver development. These protocols can usually be categorized as definitive endoderm differentiation, hepatocyte progenitor specification, and hepatocyte maturation. Older techniques used EB-based protocols to imitate gastrulation for differentiation and lineage commitment. Because of the lower efficiency associated with this method, newer protocols mainly focus on direct ES cell stimulation to increase the specificity of lineage differentiation.

ES cell stimulation is usually facilitated by the addition of different exogenous factors (e.g., cytokines) to promote differentiation in accordance with different differentiation stages (Figure 11.4). For initial induction into the definitive endoderm, the ES cells can be treated with cytokines such as Wnt3a and Activin A. Rapid hepatocyte-like cell induction and maturation can be achieved by the addition of hepatocyte growth factor (HGF). Hepatocyte specification is obtained by addition of fibroblast growth factor (FGF 2/4) and bone morphogenic protein (BMP 2/4). For induction of maturation and to stimulate the cells to express metabolic enzymes associated with mature hepatocytes, Oncostatin M (OSM) and dexamethasone can be added. These factors are commonly found during hepatic development from the septum transversum and the cardiac mesoderm, and they are thought to induce expression of hepatic markers such as alpha-fetoprotein (AFP), albumin, cytokeratin-19 (CK19), HNF4α and HNF6 (hepatocyte nuclear factor), and A1AT. It has been found that small molecules can also be used to differentiate ES cells into hepatocytes [103,121–126]

In addition to exogenous factors, techniques have been employed to improve differentiation efficiency. For example, recent studies used co-culture with various cell types such as cardiac cells, non-parenchymal liver lineages, and feeder cells to replicate the *in vivo* conditions for hepatocyte differentiation. These cell types facilitate cell-to-cell interactions [127]. For the same purpose, some studies use dextracellular matrices such as three-dimensional collagen scaffold models [128]. Recent reports suggest using microRNAs. All of this work demonstrates a huge untapped potential to improve hepatic differentiation, especially through directed differentiation of pluripotent stem cells [103].

Transcriptome analysis shows similar metabolic and phenotypic characteristics in hepatocytes derived from ES and iPS cells. However, a difference in CYP isoform expression is observed in the hepatocytes derived from them. For example, hepatocytes obtained from ES cells show enriched CYP19A1, CYP1A1, and CYP11A1 expression, while iPS cell–derived hepatocytes show enriched CYP46A1 and CYP26A1 expression [129]. For this reason, it is important that, for any given differentiation experiment using either source, a full characterization of the resulting hepatocyte population be preformed, particularly by analysis of hepatic phenotype markers through gene expression analysis, functional assays, and activity analysis, as this defines the success of a hepatic differentiation experiment. The use of iPS cells for hepatocyte derivation *in vitro* is relatively new. However, as observed in ES cells, differentiation has been successfully achieved by several groups, using similar mechanisms with comparable efficiencies. Still, more work needs to be done to develop refined protocols for obtaining more accurate hepatocyte-like phenotypes in cells derived from both ES and iPS cells [103].

With the help of iPS cells, the possibility of modeling metabolic disorders *in vitro* can be explored. This may further aid in studies of hepatotoxicity screening. To validate the use of these cells for drug safety, metabolic studies, and clinical use, however, it is important to uncover the mechanisms underlying somatic cell–derived pluripotency.

The first iPS cells were developed through retroviral insertion of the pluripotency genes Oct4, Sox2, Klf4, and c-Myc, but generation efficiency was low and the possibility of genomic insertions due to oncogenes was high [32]. Since then, several approaches have been developed for inducing pluripotency by modifying and adapting the original technique using different methods of delivery, but these approaches are as yet limited by low efficiency rates, the use of viral vectors, the need for genome insertion, and highly complex protocols, and so they are not yet well optimized. This is an important issue because high-throughput screening of compounds requires high yields of genetically uncompromised pure cells [103]. To deal with it, alternative techniques, including the use of microRNAs, are being used.

The use of the miRNA cluster miR302/367 has been shown to induce pluripotency in embryonic mouse fibroblasts, with increasing efficiency as compared to the Yamanaka technique [32,103,130]. However, because a viral vector is still needed for delivery, it remains to be seen whether the use of microRNAs can be optimized with a view to scaling up production of human iPS cell–derived hepatocytes without viral vectors. MicroRNAs induce pluripotency in somatic cells through accelerated mesenchymal-to-epithelial transition, which causes demethylation of the genome; it also allows the derived cells to maintain an epigenetic memory because of incomplete reprogramming during transformation. Incomplete reprogramming commonly occurs during early derivation and in some cases may lead to improper differentiation into unrelated cell lineages. Epigenetic faults after differentiation may be associated in redifferentiated cell types from iPS cells. Although the mechanisms associated with this are still incompletely explained, these faults may be useful in improving the efficiency, quality, and purity of iPS cell differentiation [103].

With respect to disease modeling, a recent study has demonstrated that it is possible, in a parental hepatocyte with a metabolic disorder, to induce pluripotency and redifferentiate the cell into a hepatocyte-like cell that retains the diseased phenotype. This has been demonstrated in alpha-1-antitrypsin (A1AT) deficiency, familial hypercholesterolemia, glycogen storage disease type 1α, tyrosinemia, progressive familial hereditary cholestasis, and Crigler–Najjar syndrome. Thus, the possibility exists of modeling specific disease phenotypes for new therapeutic targets [101,131]. To explore the therapeutic potential of hepatocytes derived from iPS cells in liver diseases, zinc-finger nucleases (ZFN) and piggyBac can be used to correct a point mutation in the A1AT gene, thus causing restoration of function. This result highlights the clinical potential of iPS cells in future medicine, and it offers real hope for using pluripotent stem cells from different sources to produce hepatocyte-like cells that represent the phenotypic variations among different populations. For this purpose, it is important to examine the differentiated cells' ability to behave like primary hepatocytes in metabolizing drugs. Specific markers of differentiation need to be present, and the cells should be functionally similar to primary hepatocytes in their ability to secrete urea and albumin [103].

Hepatic metabolic enzymes can be split into two main groups: phase I and phase II. The most common phase I enzyme group is the CYP family, which has been associated with the formation of reactive metabolites and is vitally important for drug metabolism. Studies of CYP in pluripotent stem cells have produced varied results, and it has been suggested that the quality of the primary hepatocytes used as reference cells may be one of the causes of the large variations encountered. Much research is focused on the ability of CYP in hepatocyte-like cells to metabolize known compounds, with results suggesting detectable metabolic activity despite variations in results [103].

Very few studies have attempted to culture hepatocyte-like cells over a longer time period. This is an area in which improvement is needed to facilitate studies dedicated to uncovering effects of drug compounds over time. The risk is that the cells may dedifferentiate in long cultures. More studies are needed in order to fully understand the differentiation patterns of hepatocytes *in vitro* [103].

ADRs, particularly the idiosyncratic type, are often due to inter individual susceptibility to drug-induced liver injury. This is an important factor to consider when developing these model systems, as pluripotent stem cell–derived hepatocyte-like cells would have originated from one donor, thereby encapsulating genetic polymorphisms of that individual only. A panel or bank of hepatocyte-like cells from randomly selected donors address this, but further investigation will certainly require significant resources [103].

11.7.2.3 *Use of Stem Cells in Neurotoxicity Studies*

Modeling of neurotoxicity is very important, as damage to neuronal cells during development may result in lifelong learning disabilities and lead to mental retardation. For this reason, models need to be developed to facilitate the screening of new chemical entities (NCE) on developing and mature neuronal cells [103].

Most current models of neurotoxicity involve the use of immortalized or cancer cell lines, with extensive work being carried out in animals and primary animal cell cultures. However, it is difficult to obtain primary human material from the brain, as brain tissue does not regenerate, so fetal, instead of adult, tissue can be used. Still, fetal tissue raises ethical concerns and its availability is limited. Normal human neural progenitor cells are commercially available as a source of primary human fetal tissue, and they have been shown to successfully differentiate into functional and metabolically active neurons, astrocytes, and oligodendrocytes in culture. Before the development of protocols to differentiate stem cells into specific neuronal cell types, most neurotoxicity screening was usually carried out using immortalized cell lines taken from neuroblastoma and embryocarcinoma tissues, or derived from primary neural tissue using different techniques [103].

Significant progress has been made in the differentiation of stem cells to neuronal cells, particularly in neurotoxicity studies. Protocols have been developed in which human ES cells and human umbilical cord blood (UBC) stem cells, as well as human fetal tissue, can be differentiated into progenitor and mature neuronal cells. Differentiated neural progenitor cells can also be successfully maintained in culture for longer periods. Recent studies have reported further refinement of differentiation protocols with neurotrophic growth factors such as NT3 and NT4, and with maintenance of cell contacts [103].

Though some progress has been achieved, demonstration of toxicity with typical neurotoxins is still in its early stages. For example, the human umbilical cord blood neural stem cell line (HUCB-NSC) was tested for its ability to model neurotoxicity at three stages of differentiation: undifferentiated, committed (2 weeks in culture without RA treatment), and lineage-directed (2 weeks in culture with RA treatment). Here, compounds including six known neurotoxins and two non-neurotoxins were used and their toxicity effect on cells was analyzed, via live/dead viability/cytotoxicity fluorescence assay (staining for markers of metabolic activity and plasma membrane integrity); MTT assay; resazurin reduction cell viability assay; nuclear chromatin staining; and immunocytochemical labeling. These revealed markers of cell proliferation, apoptotic cell death, and neural differentiation. The HUBC-NSC model was found to be successful in discriminating between neurotoxic and non-neurotoxic compounds, and its responses to the compounds used were in accordance with published observations of the effects of these compounds on commonly used PC12 cells (a cell line derived from pheochromocytoma) and cerebellar granule cells. Researchers thus concluded that HUCB-NSCs are as sensitive as other current neurotoxicity models [103,132].

Several groups have differentiated human ES cells into neuronal cells for toxicity screening. The commonly used environmental neurotoxin methylmercury (MeHg) can be successfully employed to test the predictivity of several differentiated neuronal cell lines. MeHg is found in freshwater fish and so may cause toxicity through increased membrane lipoperoxidation. ES cells were differentiated to neuronal cells using a three-step differentiation protocol: plating derived progenitor cells on fibronectin in medium containing N-2 supplement and two-step maturation using human recombinant glial–derived neurotrophic factor. Toxicity was then tested using the resazurin cell viability assay and rtPCR for key neuronal cell markers such as nestin [103,133].

This study of MeHg was the first to show how and the degree to which MeHg affects the stages of differentiation. As an alternative, MEA (microelectrode array) can be used to assay spontaneous electrical activity in neurospheres derived from ES cells because, compared to cytotoxicity assays, it is highly sensitive to changes in function before cell perturbation. One problem with MEA is that it is plating-dependent and so batch-to-batch variation may be observed.

Other toxicity end points used include rtPCR for neuronal cell markers such as musashi. Cell lines such as hN2 are ES cell–derived and can be fully differentiated into neuronal cells for toxicity screening. hN2 is as predictive of neuronal toxicity as animal models. Several neurite outgrowth inhibitors such as lithium, orthovanadate, and brefeldin A have been successfully tested using it [103].

Stem cell-derived neuronal cells have also been tested for their ability to predict neurotoxicity in a range of compounds for which it has yet to be established. For example, neural-committed stem cells have been differentiated from random humans in a five-step protocol that uses the neural growth factors NEAA and N2. Differentiation to dopaminergic neurons has been successfully carried out using medium preconditioned on the PA6 stromal cell line. Drugs such as amiodarone have been assayed in high-throughput format using an ATP assay [103].

A major benefit of stem cell-derived neuronal cells is their ability to model neuronal dysfunction. A recent study used different human ES cell lines to obtain neuronal cells using mouse stromal P6 cells as feeders, in an attempt to model the features of Parkinson's disease (PD) with 1-methyl-4-phenylpyridinium (MPP+), a drug that depletes dopaminergic neurons and thereby mimics PD's disease process [103,134].

It can be seen that developments in the use of human stem cells as models for neurotoxicity are fast progressing. These developments involve starting cell types such as human ES cells, HUCB-NSC, and neural progenitor cell lines, and the use of newer model neurotoxicants. *In vitro* models are also being tested for their capacity to predict neurotoxicity of drugs whose risk to neuronal tissue has not yet been defined. Cell viability assays, which are routinely used as an end point of neurotoxicity, are still limited in their predictive capabilities. For this reason, combinations of viability assays and analysis of other markers of cell health (i.e., functional markers and markers of apoptosis and cell death) are more useful for monitoring the effects of neurotoxic compounds. Also useful are functional assays such as neurite outgrowth and MEA to test for spontaneous electrical activity [103].

11.7.3 Use of Stem Cells for Cancer Therapy

Cancer cells grow aggressively and proliferate continuously without a check. This uncontrolled growth results in invasion and sometimes complete destruction of adjacent tissues, which may then lead to patient death. Most of the time, cancer can be treated with surgery, radiation, and chemotherapy. However, these methods may not necessarily be curative and may often lead to high patient morbidity.

Nowadays, cell-based therapies are used to treat cancer. For example, human ES cell–derived cells can be successfully differentiated into NK cells, which produce cytokines and perform antibody-mediated or direct cell–mediated cytotoxicity on target cells. In this way, they can be used in cancer therapy, possibly making use of exogenously expressed chimeric antigen receptors or T-cell receptors to recognize cancer cell antigens and direct the cytotoxic cells to kill the cancer cells in response [135,136]. Dendritic cells, which present antigens, have also been derived from ES cells and have been used for targeting cancer cells.

For successful cancer treatment, genetic manipulations of ES cells are needed and further investigation is required. Recent studies have shown that the conditions and medium used for culture of human ES cells inhibits tumor growth. Also, it has been reported that the microenvironment of human ES cells neutralizes the expression of Nodal, an embryonic morphogen, in aggressive tumor cells and further inhibits tumor growth. These findings provide many new ways to use human ES cells in the treatment of cancer [136].

Despite their powerful differentiation capacity and relatively easily *ex vivo* culture characteristics, there are several key problems with human ES and iPS cells that must be overcome before they can be used in clinical applications. One such problem involves ethical concerns, which have limited research on this cell type. Even though human iPS cells overcome these ethical concerns, the efficiency of their generation still needs improvement. Also, they must be better characterized and their pluripotency established. In initial studies, both cell types were typically cultured on inactivated mouse embryonic fibroblasts (MEFs), which makes them inappropriate for clinical use because of xenogenic component contamination. However, improved culture systems use feeder-free conditions suitable for cell culture and maintenance.

It is difficult to achieve efficient differentiation of pluripotent stem cells because, in general, they induce teratoma formation. Their use in therapeutic applications thus remains a hurdle given that, within a population of differentiated stem cells, only a few undifferentiated cells are enough to form teratomas. Also, even though teratoma formation can be easily monitored, its incidence and mechanisms are not well understood, and few tools are available to eliminate it. Unless techniques are developed to completely shut down or control the pluripotency of undifferentiated stem cells in a population of differentiated cells, the undifferentiated cells will remain dangerous if used for therapy in humans. For this reason, much current research is focusing on developing better and more efficient methods for generating a homogenous and fully differentiated cell population derived from pluripotent stem cells.

Human ES- or iPS-derived cells in therapeutic treatment may still undergo immune rejection. If iPS cells are generated from and used in the same donor, this problem should be avoided, but it is still not well established whether, during the differentiation process, immunogenic molecules might be induced and expressed along the way. Such problems can be overcome by immune-suppressing drugs or genetic modifications of the pluripotent stem cells to improve immune tolerance; however, these solutions may have unwanted side effects.

Another way to overcome the problem of immune rejection is through cell banks of pluripotent stem cells based on HLA typing for matching these cells to patients. Of course, broad-based and large-scale information processing will be required to create such a useful database, but the safety of pluripotent stem cells in clinical applications will be improved. Also, banking will allow exploration of third-party cells for reprogramming, which may actually be a benefit since it is known that not all somatic cells can be reprogrammed with the same efficiency. Thus, cell sources that are abundant, easily available, and more efficiently reprogrammed can be used for human pluripotent stem cell generation, including fetal somatic cells. In this way, they can be further expanded and thus further extend the applicability of this revolutionary technology [136].

11.8 FUTURE PROSPECTS

The initial report on the reprogramming of somatic cells into iPS cells was followed by a remarkable upsurge in stem cell research. However, despite steady progress, crucial problems must be overcome for the field to realize its full potential. For one, differentiation protocols must be optimized to obtain reliable and safe cells. The increase in reprogramming efficiency was achieved without genetic cell modification, but the protocols used should be subject to rigorous quality control to maintain consistency and reproducibility so that reprogrammed cells can be effective in clinical settings. Also, genomic alterations that take place during reprogramming must be understood so that the derived cell populations will be pure, functional, and suitable for both research and therapy. To this end, it is important to minimize aberrations and generate more stringent pluripotency markers.

Refined differentiation protocols will help researchers investigate the pathophysiological basis of genetic diseases and carry out drug screening on affected cell types. Additionally, these protocols will facilitate derivation of patient-matched cells and tissues for clinical transplantation, which has been the main ambition of the stem-cell community and may be the ultimate measure of success in the field [137]. Moreover, because the use of iPS cells for drug development and testing requires patient-specific disease models, pluripotent stem cells may, in the future, aid the development of regenerative therapies by correcting cells with genetic disorders and further testing the functional capacity of these cells *in vivo* [138].

Pluripotent stem cells offer an intriguing tool for the study of mechanisms underlying various diseases as well as for the testing of various drugs against them. Pluripotent stem cell technology will eventually act as a boost to regenerative medicine by exploring various sources of unlimited cell populations to be used in clinical therapeutic settings.

ABBREVIATIONS

3C	chromosomal conformation capture
A1AT	alpha 1 anti-trypsin
AD	Alzheimer's disease
ADP	Adenosine Diphosphate
ADR	adverse drug reaction
AF	amniotic fluid
AFP	alphafetoprotein
AG	agamous
ATP	adenosine triphosphate
ATX	Ataxin
bFGF	basic fibroblast growth factor
BM	bone marrow
BMP	bone morphogenic protein
BS-seq	bisulphite sequencing
CD	cluster of differentiation
CFU-f	colony-forming unit of fibroblasts
CK	cytokeratin
CpG/CG	phosphodiester bond between cytosine guanine
CYP	cytochrome P
DDT	dichlorodiphenyltrichloroethane
DMEM	Dulbecco's modified essential medium
DMSO	dimethylsulfoxide
DNA	deoxyribonucleic acid
EBs	embryoid bodies
EDTA	ethylenediaminetetraacetic acid
EED	embryonic ectoderm development
EG	embryonic germ
EGF	epidermal growth factor
EMF	electromagnetic field
END2	endoderm-like cell 2
ENU	*N*-ethyl-*N*-nitrosourea
ES	embryonic stem
EZH2	enhancer of zeste
FACS	fluorescence-activated cell sorting
FBS	fetal bovine serum
FD	familial dysautonomia
FGF	fibroblast growth factor
FH	familial hypercholesterolemia
gPS	germline-derived pluripotent stem
GSCs	germline stem cells
hERG	human *ether-à-go-go*–related gene
HGF	hepatocyte growth factor
HLA	human leukocyte antigen
HNF	hepatocyte nuclear factor
HSCs	hematopoietic stem cells
HUCB-NSC	human umbilical cord blood–neural stem cell line
IC	imprinting center
ICM	inner cell mass
IGF1	insulin-like growth factor 1
IKBKAP	inhibitor of kappa light polypeptide gene enhancer in B cells, kinase complex-associated protein
IMDM	Iscove's modified Dulbecco's medium
iPS/C	induced pluripotent stem/cell
Klf4	Kruppel-like factor 4
KOSR	knockout serum replacement
LDL	low-density lipoproteins
LEOPARD	lentigines, ECG anomalies, ocular hypertelorism, pulmonic stenosis, abnormal genitalia, retarded growth and sensorineural deafness
LRRK2	leucine-rich repeat kinase 2
MEA	microelectrode array
MeCP2	methyl CpG-binding protein 2
MEF/s	mouse embryonic fibroblast/s
MEFC2C	myocyte enhancer factor 2
MeHg	methylmercury
MethylC-seq	methylC sequencing
MMC	mitomycin C
MNNG	*N*-methyl-*N*-nitro- *N*-nitrosoguanidine
MPP	1-methyl-4-henylpyridinium
MSC	mesenchymal stem cell
MTT	3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide
MYH7	myosin-heavy polypeptide 7
N-2	neutropan-2
NCE	new chemical entity
NEAA	nonessential amino acid
NKX2.5	NK2 Transcription Factor-Related
NT	neurotrophic
Oct4/OCT4	octamer-binding protein 4
OSM	oncostatin M
PC	pheochromocytoma
PcG	polycomb group
PD	Parkinson's disease
pES	parthenogenetic embryonic stem
PKL	Paxillin Kinase Linker
PRC	polycomb repressive complex
QT	Q wave T wave
RA	retinoic acid
RC	Repressive Complex
RNA	ribonucleic acid
ROCK	rho-associated protein kinase
rtPCR	real-time polymerase chain reaction

SAND	Sp100, AIRE-1, NucP41/75, DEAF-1
SCZD	schizophrenia
SMA	spinal muscular atrophy
SMN1	survival motor neuron 1
Sox2/SOX2	SRY (sex-determining region Y)-box 2
SSC	spermatogonial stem cell
SSEA4	stage-specific embryonic antigen 4
SUZ12	Suppressor of Zeste 12
TGF-β	transforming growth factor-β
TrxG	trithorax group
UCB	umbilical cord blood
UCMSC	umbilical cord matrix system cell
UCPVC	umbilical cord perivascular cell
UCSCs	umbilical cord stromal cells
ULT	ULTRAPETALA
ZFN	zinc-finger nuclease

Chapter 12

Fundamentals of Complex Trait Genetics and Association Studies

Jahad Alghamdi and Sandosh Padmanabhan
Institute of Cardiovascular and Medical Sciences, College of Medical, Veterinary and Life Sciences, University of Glasgow, UK

Chapter Outline

12.1 Overview 235
12.2 The Phenotype 235
  12.2.1 Intermediate Phenotypes and Endophenotypes 236
  12.2.2 The Standardized Phenotype 237
  12.2.3 Assessment of the Genetic Basis of a Trait 237
  12.2.4 Familial Aggregation 237
  12.2.5 Recurrence Risk 237
  12.2.6 Heritability 237
12.3 Population Genetics 239
  12.3.1 Linkage Disequilibrium 241
  12.3.2 Linkage Studies 243
12.4 Association Studies 247
  12.4.1 Association Study Designs 247
  12.4.2 Population-Based Study Designs 249
  12.4.3 Correction for Multiple Testing 253
  12.4.4 Imputation 254
  12.4.5 Validation and Replication 255
  12.4.6 Meta-Analysis 255
  12.4.7 Fine Mapping and Resequencing 255
  12.4.8 Reporting of GWA Studies 256
12.5 Conclusions 256
References 256

12.1 OVERVIEW

There is significant inter-individual variability in drug response, much of which may have a genetic basis. This implies that genotype can influence drug metabolism, drug transport, and adverse drug reactions. A major aspect of pharmacogenomics involves using DNA sequence data to predict drug response and to inform drug discovery and development. This requires an understanding of population genetics and the methods available for gene mapping. In this chapter, we provide an outline of the principles of population genetics that underlie the analytic methods used in relating DNA sequence variation to drug response. We provide extracts from useful reviews that provide more detail on the concepts presented here.

12.2 THE PHENOTYPE

Phenotype or trait is the observable or measurable characteristic that is the target of genetic dissection. In pharmacogenomic studies, this can be measures of drug efficacy, side effects, or outcomes, and can be either quantitative or qualitative. The genetic architecture of a trait refers to all the genetic and environmental factors that contribute to the trait, as well as their magnitude and their interactions. The prevalence of the trait in the population is calculated as the phenotype frequency, which is the ratio of the number of individuals with a particular phenotype to the total number of individuals in the population. Phenotype frequency is a parameter that is usually calculated to determine whether the phenotype is common or rare (See Figure 12.1).

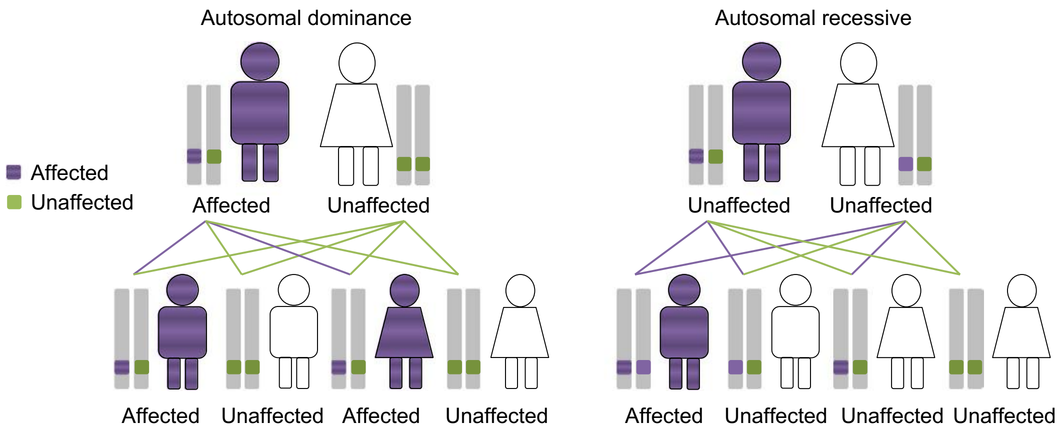

FIGURE 12.1 **Autosomal dominant and recessive inheritance.**

TABLE 12.1 **Simple versus Complex Traits**

	Simple	Complex
	• Single gene • Clear pattern of inheritance • Complete penetrance • No phenocopies	• Aggregate in families but do not segregate in Mendelian fashion • Multigenic • Multiple environmental factors • Phenotypic and Genetic heterogeneity • Phenocopies • Variable penetrance • Often not deleterious mutations, but natural variations frequent in the population • Complex interplay between genetic and environmental factors
Main problems	Genetic heterogeneity, pedigree size	Many unknowns about genetic basis: number of loci, number of alleles, allele frequency, risk or protection, interaction
Analysis	Parametric linkage analysis the method of choice: most powerful and not sensitive to allelic heterogeneity	Multitude of approaches with almost no ideal solution

A phenotype can be simple or complex and the characteristics of both are summarized in Table 12.1. Simple traits are rare, usually have a monogenic basis, and are due to a single gene with a large effect and high penetrance. Simple traits manifest Mendelian patterns of inheritance and can be expressed as dominant or recessive. Complex traits in contrast are more common, have a multifactorial etiology, and are due to numerous genes, environmental factors, and their interactions. Complex traits do not segregate within extended pedigrees in a straightforward Mendelian fashion.

Phenotypes can be dominant (when the trait is expressed in the presence of one copy of the allele) or recessive (when the trait is expressed only in homozygous form with two copies of the risk allele). The phenotype is co-dominant if both alleles are expressed in the heterozygous state.

12.2.1 Intermediate Phenotypes and Endophenotypes

In pharmacogenomics, the complexity of the processes that affect drug response and toxicity makes the selection of the right phenotype for study challenging. This is because a single disorder on a clinical level may actually be a heterogeneous group of potentially overlapping disorders on a genetic or etiologic level. All methods of gene localization, for example association studies, are sensitive to locus heterogeneity in which different genes contribute to phenotypic variation in different subsets of individuals. Association studies are also sensitive to allelic heterogeneity in which different variants in the same locus influence phenotype variation.

One strategy for dealing with underlying genetic heterogeneity, and a potentially complex network of etiologies contributing to phenotype variation, is to directly study quantitative risk factors that may index different underlying aspects of disease etiology. These are called intermediate phenotypes and they may be genetically less complex with potentially stronger genetic signals. The term "endophenotype" was coined in 1966 to distinguish between exophenotype (external) and endophenotype (internal) [1]. In general, an endophenotype must meet the following criteria: (1) it is linked to an illness in a population; (2) it is heritable; (3) it manifests itself whether or not the illness is active; and (4) it co-segregates with an illness in families [2].

It is generally easier to focus on a small group of genetic variants that have a large effect on the endophenotype. The closer a phenotype is to the level of gene action, the larger we might expect the genetic effects to be. For example, myotoxicity is the most common adverse effect of statins. Its pathophysiology is not fully understood, but it is likely to involve multiple pathways. Therefore, toxicity is defined in clinical trials by looking at a proxy, creatine kinase levels, which, if greater than tenfold the normal value, indicate toxicity; this is more tractable for genetic analysis [3]. Similarly, the readout for the toxic effect caused by inhibitors of the vascular endothelial growth factor (VSP) signaling pathway (e.g., sorafenib) is hypertension, so blood pressure can be used as an endophenotype for this toxicity [4].

12.2.2 The Standardized Phenotype

Accurate and standardized phenotyping is a vital initial step in genetic dissection of pharmacogenomic traits [5]. For example, given the relatively rare incidence of serious ADRs, only small numbers of well-phenotyped patients can be identified from a single center, necessitating the pooling of samples from multiple centers, often from different countries. A standardized phenotype thus becomes crucial for accurate pooling of data. Without a sufficiently large patient database, it would not be possible to identify genetic factors of modest effect or by ethnicity. Another critical point is that phenotypic misclassification may dilute or even mask a significant association with a gene locus, or it may provide a false-positive association. To help standardize phenotypic definitions, the Phenotype Standardization Project (PSP) was established to define in detail three serious forms of adverse drug reactions (drug-induced liver injury, drug-induced skin injury, and drug-induced *torsade de pointes*) that are used in GWAS [5]. The adoption of common phenotypic criteria is likely to benefit future research efforts, whether conducted by academic institutions, pharmaceutical companies, or regulatory bodies. The aim is creating a robust—and ultimately predictive—pharmacogenomic database that is relevant for all ethnicities [5].

12.2.3 Assessment of the Genetic Basis of a Trait

Familial aggregation analyses are traditionally used to obtain indirect evidence for a genetic contribution to a trait, by estimating the trait's heritable component. Heritability is the proportion of phenotypic variation due to the genetic differences between individuals within a population, and estimates of heritability can be used to describe the relative components of variance attributable to genetic and environmental factors [6,7].

12.2.4 Familial Aggregation

A shared genetic etiology for a trait means that family members are likely to share variants that influence the trait. In theory, phenotypes correlated with a particular risk allele should also be correlated among family members; this will lead to lower phenotypic heterogeneity [8]. Different metrics are used to quantify familial aggregation. If the phenotype is a binary trait coded for response or adverse effect, for example, the heritable component's recurrence risk ratio is calculated; on the other hand, if the trait is continuous, correlation or covariance-based measures such as the intra-family correlation coefficient (ICC) are used [6]. It is important to understand that assessment of familial aggregation takes no account of underlying biology. This means that evidence of familial aggregation does not always imply genetic effects. However, as most nongenetic factors associated with complex traits are weakly correlated in relatives and have only modest affects, the magnitude of familial aggregation can be considered to have a predominantly genetic basis.

12.2.5 Recurrence Risk

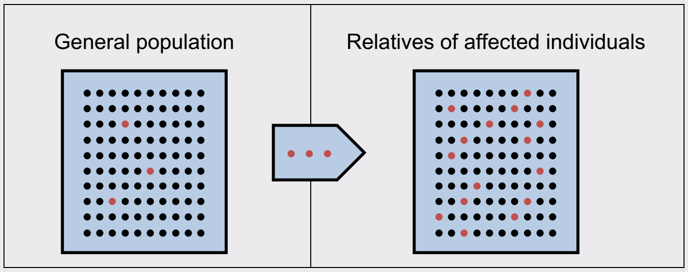
For a binary phenotype, the recurrence risk ratio (λ_R) is the ratio of disease prevalence in relatives (P_R) to the disease prevalence in the general population (P). λ_R can be estimated across different types of relatives; for example, λ_S (siblings) is the most common form. Measuring λ_R provides valuable information about the genetic component of the trait, and it is an important determinant of the power of affected relative pair studies to detect linkage (See Box 12.1).

12.2.6 Heritability

The heritability of a continuous trait is defined as the proportion of its total variance (σ_T^2) attributable to genetic

BOX 12.1 Calculation of Recurrence Risk

Disease prevalence (in percentage) is the number of individuals affected by a disease in a given population out of a total of 100 individuals at a particular time. Thus, 3 affected $=0.03$ and 15 affected $=0.15$. The recurrence risk for siblings (λ_S) is therefore $\lambda_S = 0.03/0.15 = 5$.



Examples of λ for Some Diseases

Type	Disease	P Relatives	P General	λ
Mendelian disorders	Cystic fibrosis	0.25	0.0004	500
	Huntington's disease	0.5	0.0001	5000
Complex disorders	Multiple sclerosis			~25
	Type 1 diabetes			~25
	Type 2 diabetes			~3.5

Complex diseases tend to have low λ, which reflects many genes, each contributing a small effect. Mapping is easier for traits with high λ, which suggests a major disease gene.

In late onset diseases, care should to taken that any systematic differences in the age distribution of the siblings of the affected cases and the the age distribution of the population sample from which population prevalence was estimated do not distort the statistic.

In relation to diseases with high population prevalence, such as asthma, λ_s has a theoretical upper bound at 1/prevalence, which means that one should be cautious in comparing values between populations that have different prevalences.

factors in a particular population. Narrow sense heritability (h^2) is defined as σ^2_A/σ^2_T, and broad sense heritability (H^2) is defined as σ^2_G/σ^2_T, where σ^2_A includes the additive genetic components of variance and σ^2_G includes all genetic components of variance [7]. For binary traits, heritability is usually calculated by invoking a hypothetical construct known as liability and applying a version of variance components modeling. Liability is an underlying, unobservable, normally distributed trait that is assumed to determine the probability that an individual will develop the disease of interest.

The main point to note here is that the numerator has a simple genetic meaning, but the denominator $-\sigma^2_T$ captures the variance attributable to genes and shared environment as well as residual variance attributable to unshared and unmeasured determinants and measurement error. Consequently, for a given trait heritability can vary quite substantially from study to study depending on the population being investigated as a result of varying environmental exposures between populations, the structure of the analytic model, and measurement error. If a disease process is entirely dependent on the presence of a particular allele of a particular gene, but all individuals in the population are homozygous for that allele, variation at that locus plays no role in variation in disease phenotype and therefore makes no contribution to heritability. On the other hand, the gene is clearly implicated in the causal architecture of the disease. Equivalently, a near ubiquitous environmental exposure makes little or no contribution to the denominator σ^2_T.

The power of most studies for discovering genes is positively associated with the heritability of the trait of interest. Thus, all else being equal and if the option exists, analytic efficiency may be enhanced by selecting a study population

TABLE 12.2 Heritability of Common Traits

Disease	Study Type	Heritability
High blood pressure	Twin studies	0.60
Asthma		0.72–0.8
Type 1 diabetes		0.72
Type 2 diabetes		0.26
Rheumatoid Arthritis		0.32
Body mass index	Family studies	0.34
Waist-to-hip ratio		0.28
Fasting glucose		0.33
Fasting insulin		0.23
Fasting triglyceride		0.47
Fasting high-density lipoprotein (HDL)		0.48
Systolic blood pressure (SBP)		0.30

in which heritability of the trait of interest is thought to be high. While the proportion of variance explained by genetic factors can provide insight into the value of genetic studies, it is important to note that heritability estimates do not provide information on the direction of effect of these factors or insight into their utility in prediction (See Table 12.2).

12.2.6.1 Heritability of Pharmacogenomic Traits

Studies in families can determine if common human disease phenotypes, like myocardial infarction or asthma have a heritable component. However, it is usually not possible to accumulate well-defined drug response phenotypes across multiple related patients with the same disease; as a result, the heritable component of variability in drug action may not be well-defined. One study used an *in vitro* approach where lymphoblastoid cells lines from related subjects were exposed to anticancer drugs, and the heritability of cytotoxicity was estimated at 25–65% [9,10]. Another approach is to quantify drug responses in multiple healthy members of a family—for example, twins. In twins, urinary excretion of isoniazid was found to be more variable in dizygotic twins compared to monozygotic twins; also, digoxin clearance was better correlated within monozygotic than dizygotic twins. Both findings indicate that shared genetic factors play a role in the expression of these drug related traits. The heritability of digoxin area under the curve was >79% [6]. In a study of the Amish—a founder population with extensive genealogical records—ADP-stimulated platelet aggregation showed a heritability of 33% at baseline and 73% after administration of clopidogrel, indicating a strong genetic component in clopidogrel drug response [11].

The heritabilities of some pharmacogenomic traits are presented in Table 12.3. If genome-wide genotype data are available for unrelated individuals, then there is the option to use linear mixed models to estimate the proportion of heritability explained by SNPs [12]. This can help determine the heritability of drug efficacy or toxicity especially from data in clinical trials.

12.3 POPULATION GENETICS

Population genetics is the study of Mendelian genetics at the level of a whole population. Genetic variants are classified according to their frequency or their nucleotide composition. Based on the minor allele frequency (MAF) in the population, a genetic variant is classified as common if its MAF is greater than 1%, or rare if its MAF is less than 1%. Common variants are also called polymorphisms (See Figure 12.2).

Single-nucleotide polymorphisms (SNPs) are the most prevalent class of genetic variation among individuals. It is estimated that the human genome contains ~11 million

FIGURE 12.2 **Types of genetic variations.** Single-nucleotide polymorphisms are a substitution of a single base pair in the DNA sequence. The insertion-deletion variants (indels) represent insertion or deletion of at least one base-pair in the DNA sequence. Block substitutions occur when a string of adjacent nucleotides varies between two genomes. Inversion variants describe the reversed order of nucleotides in a defined section. The copy number variants are repetitions of an identical sequence in some chromosomes. *Source: From Frazer et al.* [13]. *Reprinted with permission from Macmillan Publishers Ltd.*

SNPs, about 7 million of which have a MAF greater than 5%; the remaining have a MAF falling between 1% and 5%. Most of these SNPs are cataloged in the public dbSNP database and designated by a reference number. High-frequency SNPs are not expected to exert any major phenotypic effect because natural selection should ensure that SNPs are eliminated if harmful or fixed if beneficial. A genetic structural variant is any change in the human genome that involves more than a single nucleotide; such changes include insertion-deletion (indels), block substitutions, inversions of

DNA sequences, and copy number variants (CNVs) [13]. Four main factors make SNPs preferable to other types of genetic variations for dissecting the genetic basis of common diseases [14]. First, they are the most common and can be found throughout the genome, in exons, introns, promoters, enhancers, and intragenic regions, and some of them may themselves be functional. Second, when adjacent they show patterns of correlation that can enhance gene mapping and highlight recombination hotspots. Third, differences in their allele frequencies between different populations can be used in population-based genetic studies. And, fourth, they are more stable than other types of genetic variation, allowing more consistent estimates of genotype-phenotype associations.

12.3.1 Linkage Disequilibrium

Because the mutation rate is low (around 10^{-8} per site per generation) when set beside the most recent common ancestor of any two individuals (around 10^4 generations) [15], most SNPs are thought to arise from a single historical mutational event [14]. When a variant is first introduced into a population by mutation, it is perfectly correlated with nearby variants and is said to be in linkage. Linkage is the tendency of genes or other DNA sequences at specific loci to be inherited together as a consequence of their physical proximity on a single chromosome. Genetic recombination occurs when two homologous chromosomes exchange parts of their DNA during meiosis so that new combinations of alleles can be passed on to the next generation (see Chapter 2).

Recombination occurs at random. If there is a large distance between two segments of DNA, there is a good chance that recombination will occur between them. However, if the two sequences are close together, recombination will rarely occur between them—that is, the two sequences will tend to stay together rather than being split apart by recombination. In the latter case, the recombination frequency is low and the two DNA sequences are considered to be linked. High recombination frequencies are found for DNA sequences far enough apart that they are not linked to each other and therefore are considered to be in linkage equilibrium (i.e., both loci are segregating independently).

When a particular allele at one locus is found together on the same chromosome with a specific allele at a second locus—more often than expected if the loci were segregating independently in a population—the loci are in disequilibrium. Linkage disequilibrium (LD) is defined as the nonrandom association of alleles in adjacent loci, and following on from the preceding explanation, loci that are close to each other will be less likely to be split apart by recombination and thus be in linkage disequilibrium rather than equilibrium (Figure 12.3).

FIGURE 12.3 Linkage and linkage disequilibrium. Within a family, a recombination occurs during meiosis in the germ cell between the paternal chromosome (blue) and the maternal chromosome (yellow). The offspring carry a recombinant chromosome, which undergoes further recombination in the next generation. In generation 3, the two markers (red triangles) in the ancestral (yellow) region are said to be in linkage. Within a population, the stretches from the ancestral chromosomes are decayed by recombination events over the time. At some point, a recombination event occurs between every possible point in the chromosome, which leads the population to move from LD to linkage equilibrium. *Reproduced with modifications Bush and Moore* [17].

When a variant is first introduced by mutation, it is in perfect LD (correlation) with its neighbouring loci. However, over successive generations this perfect correlation tends to break up (LD decay) due to a several reasons including recombination between the two loci, gene conversion, genetic drift, population growth, admixture, population structure, natural selection, variable recombination, and mutation rates [14,16].

A variety of statistics have been proposed to measure the amount of LD. The two most commonly used measures are D′ and r^2. The higher the value of D′, the lower the possibility that a recombination event occurred between these two loci. ($D' = 1$ means that the two markers have not been separated by a recombination event.) The absolute value of r^2 is more commonly used to quantify and compare LD in the context of mapping. When $r^2 = 1$, the two markers have not been separated by recombination and have the same allele frequency. In this case of perfect LD, the two markers are completely linked and observation at one marker provides complete prediction about the other. If the r^2 value between the causal marker and the tag SNP is less than 1, the sample size must be increased by $1/r^2$ of the sample size required for detecting the direct association with the disease's allele (See Box 12.2).

LD plays a fundamental role in gene mapping, both as a tool for fine mapping of complex disease genes and in genome-wide association studies. LD is also of interest for what it can reveal about evolution of populations. The rate of LD decay depends on population size, the number of founding chromosomes in the population, and the number of generations for which the population has existed [17]. For this reason, the pattern of LD differs among populations. For instance, African populations have smaller regions of LD because they are the most ancestral and so more recombination events have occurred. European and Asian populations have larger regions of LD because they were created by founder events that altered the number of founding chromosomes as well as population size, and generational age (See Box 12.3).

The international HapMap project has constructed genome-wide maps of LD patterns in multiple populations [15]. One of its main objectives is to identify set of SNPs that are in LD blocks to allow more efficient genotyping. These LD blocks vary in size but are typically 5–15 Kb and cover only 67–87% of the examined genomic regions. Interestingly, despite the great number of human DNA variants, human variability is much lower than expected, as each population has 4–5.6 haplotypes that account for 93–95% of copies of any given blocks. Thus, a small number of SNPs, called "tag SNPs", can be typed in each block to identify it (Figure 12.4). This implies that a limited set of SNPs (~500,000–1,000,000 SNPs) can capture ~90% of the genetic variation in the population [16]. Coverage is a measure of how well the SNPs that are part of a genotyping set capture all known variants; it is an important factor not only in the ability to capture all causal variants but also in terms of study power. The maximum r^2 (the squared correlation coefficient for each SNP) can be used to translate coverage to the sample size required for an indirect association study. For a particular variant, the effective sample size of such a study is simply the product of the actual sample size and the maximum r^2 value of the variant. Thus, as coverage decreases, a larger sample size is needed to obtain the same power. In turn, the overall power of a GWA study can be estimated using the effective sample size for each variant.

12.3.1.1 Hardy-Weinberg Equilibrium

In 1908, two scientists—Godfrey H. Hardy, an English mathematician, and Wilhelm Weinberg, a German physician—independently worked out a mathematical relationship that related genotypes to allele frequencies called the Hardy-Weinberg principle, a crucial concept in population genetics. It predicts how gene frequencies will be inherited from generation to generation given a specific set of assumptions. When a population meets all the Hardy-Weinberg conditions, it is said to be in Hardy-Weinberg

BOX 12.2 Applications of Linkage Disequilibrium Metrics

Several metrics have been devised to measure linkage disequilibrium (LD). The two most common are D′ and r^2. Both are related to D, the basic unit of LD.

D

D measures the deviation of haplotype frequencies from the equilibrium state. LD occurs when D is significantly greater than zero. Consider two linked SNPs with alleles (A, a) and (B, b), resulting in four possible haplotypes: AB, Ab, aB, and ab. D can be calculated as in equation 1, where f(X) represents the frequency of the X allele or haplotype.

$$D = f(AB) - f(A)\,f(B)$$

D′

D′ is the absolute ratio of D compared with its maximum value, D_{max}, when $D \geq 0$ or when compared with its minimal value,

D_{min}, when $D < 0$. $D' = 1$ denotes complete LD, and historical recombination results in its decay of toward zero.

r^2

r^2 is the statistical coefficient of determination—it measures correlation between a pair of variables.

$$r^2 = \frac{D^2}{f(A)\,f(a)\,f(B)\,f(b)}$$

r^2 is of particular importance in genetic mapping because it is inversely related to the required sample size for association mapping, given a fixed genetic effect. For example, if only one of a pair of SNPs is genotyped and r^2 between the SNPs is found to be 0.5, then, to provide the same statistical power for the ungenotyped SNP compared with the case where $r^2 = 1$, the sample size needs to be doubled. When $r^2 = 1$, knowing the allele genotypes of one SNP is directly predictive of the genotypes of another SNP. The alternative notation R^2 is used when individual variables are predicted using the multiple regression of a constellation of other variables.

Relationship between D' and r^2

D' and r^2 can be written in terms of each other and in terms of allele frequencies. Without losing generality, the four alleles can be chosen such that $D \geq 0$ and $f(A) \geq fB$. Thus, D' and D_{max} have the relations.

$$D' = \frac{D}{D_{max}}$$

$$D_{max} = f(a)f(b)$$

and

$$r^2 = (D')^2 \times \frac{f(a)f(B)}{f(A)f(b)}$$

This equation shows the relationship between D' and r^2 and allele frequencies. $f(A) \geq fB$, r^2 has the upper bound of $(D')^2$ and reaches it only when $f(A) = f(B)$, which implies that D', a commonly used measure of historical recombination, provides information on the physical extent of useful LD (in terms of association mapping and statistical power) by providing the upper limit of r^2. Dense LD maps based on high-frequency SNPs ($MAF > 0.1$) can reveal regions of historical recombination. Knowing the level of D' decay in these maps directly provides the maximum potential level of useful LD in association mapping (based on r^2) for high-frequency SNPs, even if a significant number of common SNPs remain undiscovered. For example, if a recombination point results in a D' of 0.7 for SNPs on either side of it, the maximum possible r^2 for these SNPs is 0.49, and sample sizes need to be more than doubled to maintain the same statistical power for association mapping. It should be noted that both D' and r^2 suffer from sampling biases given a small number of individuals and rare variants. Confidence intervals for D' have been used by some investigators.

equilibrium (HWE). Human populations do not meet all the conditions of HWE exactly, and their allele frequencies will change from one generation to the next, so the population evolves. How far a population deviates from HWE can be measured using the "goodness-of-fit" or chi-squared test (χ^2) (See Box 12.4).

12.3.1.2 *HWE in Association Studies*

When marker allele frequencies in controls deviate markedly from HWE, this is commonly taken as an indicator that the genotyping is unreliable [18] or that there is marked population stratification (see the following). A slight departure from HWE may also be indicative of selection, in which case there will be deviation from HWE at loci associated with disease. Removing such loci should be carefully considered. The threshold of HWE should be carefully considered as well, particularly in the setting of GWA studies where a large number of SNPs are expected to deviate from HWE only by chance. For example, a GWA study that genotypes 500,000 SNPs may, by chance, have 25,000 SNPs with a p-value <0.05 for HWE. Therefore, a stricter threshold is required for GWA studies to identify worrisome HWE deviation.

12.3.2 Linkage Studies

The purpose of linkage analysis is to search for alleles or chromosomal segments shared by affected relatives more so than expected by random Mendelian segregation. These segments are passed entirely from the parents to the offspring without recombination at meiosis. At gamete formation, the gamete receives a mixture of the two homologous chromosomes because of crossover events. Crossovers can split alleles that lie together on a common parental chromosome, resulting in alleles that originally came from different grandparents on the same chromosome. The number of crossover sites in the human genome is thought to follow a Poisson distribution (averaging around 35 crossover points), and their locations are generally random and independent of each other. Cosegregation should therefore be detectable for marker loci quite far away from the disease-causing variant. Because linkage operates over long genetic distances, a

BOX 12.3 Differences among Populations in the Linkage Disequilibrium of Common Variants in the Human Genome

The LD structure of SNPs in a 13 kb interval of chromosome 9p21 is shown in the accompanying figure for the three HapMap populations: CEU (European ancestry), JPT + CHB (Asian ancestry), and YRI (African ancestry). Two commonly used definitions of LD, D′ and r^2, capture different aspects of nonrandom association. On the left of the figure, the LD structures of the interval are shown quantified using D′. SNPs ascertained in phase II of the HapMap Project with a minor allele frequency (MAF) ≥5% are shown in their respective map positions. There are population differences in the numbers of SNPs that meet the ≥5% criterion. The pairwise correlations of SNPs—which are shown as vertical lines—appear as red and white boxes, with red indicating high correlation ($D' \approx 1$) and white indicating no correlation ($D' \approx 0$) (other colors represent intermediate values). On the right, all SNPs appear in the bottom row as black triangles. Above this row, the SNPs are grouped into bins at an $r^2 > 0.8$ (using the ldSelect algorithm). SNPs that are efficiently tagged by each other ($r^2 > 0.8$) are in the same color and are connected by a line. Singleton bins that do not tag any other SNPs appear as individual blue triangles.

Using both r^2 and D′, it is clear that LD is less strong in the African population than in the Caucasian and Asian populations. This reflects the fact that some haplotype patterns across the genome were lost in population bottlenecks associated with human migration out of Africa. Using the D′ statistic, fewer SNPs are correlated, as indicated by fewer red boxes and more white boxes. Using the r^2 statistic, Africans show a greater number of singleton SNPs and the LD bins have fewer numbers of variants and span shorter lengths. The r^2statistic reveals greater differences in pairwise correlations between SNPs in all three populations because the allele frequencies vary substantially among them. For example, in Caucasians, SNP rs10757278 (purple box), which is associated with myocardial infarction, lies in a bin of eleven SNPs; in Africans, rs10757278 is in LD with three of these SNPs, and in Asians it is in a singleton LD bin. For rs10757278, the MAF is the same in Caucasians and Asians (50%) but considerably less in Africans (5%).

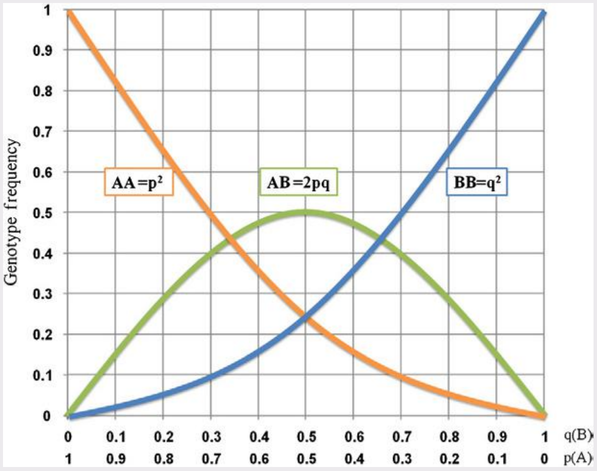
FIGURE 12.4 **Haplotype and tagged SNPs.** (A) A short stretch of DNA from four versions of the same chromosome region in different individuals. Most of the DNA sequence is identical in these chromosomes, but three bases are shown where variation occurs. Each SNP has two possible alleles; the first SNP in has the alleles cytosine and thymine. (B) A haplotype is made up of a particular combination of alleles at nearby SNPs. Shown here are the observed genotypes for 20 SNPs that extend across 6000 DNA bases. Only the variable bases are shown, which include the three SNPs that are shown in (A). For this region, most of the chromosomes in a population survey turn out to have haplotypes 1–4. (C) Genotyping just three tagged SNPs out of 20 is sufficient to uniquely identify these four haplotypes. For instance, if a particular chromosome has the pattern A-T-C at these three tagged SNPs, this pattern matches the pattern determined for haplotype 1. *Source: International HapMap Consortium* [34]. *Reprinted with permission from Macmillan Publishers Ltd.*

BOX 12.4 Hardy-Weinberg Equilibrium

The distribution of genotypes in a population in Hardy-Weinberg equilibrium can be graphically expressed as shown in the accompanying graph. The x-axis represents a range of possible relative frequencies of A or B alleles. The coordinates at each point on the three genotype lines show the expected proportion of each genotype at that particular starting frequency of A and B.



To check for HWE:

- Consider a single biallelic locus with two alleles A and B with known frequencies (allele A = 0.6; allele B = 0.4) that add up to 1.
- Possible genotypes: AA, AB and BB
- Assume that alleles A and B enter eggs and sperm in proportion to their frequency in the population (i.e., 0.6 and 0.4)
- Assume that the sperm and eggs meet at random (one large gene pool).
- Calculate the genotype frequencies as follows:
  - The probability of producing an individual with an AA genotype is the probability that an egg with an A allele is fertilized by a sperm with an A allele, which is 0.6 × 0.6 or 0.36 (the probability that the sperm contains A times the probability that the egg contains A).
  - Similarly, the frequency of individuals with the BB genotype can be calculated (0.4 × 04 = 0.16).
  - The frequency of individuals with the AB genotype is calculated by the probability that the sperm contains the A allele (0.6) times the probability that the egg contains the B allele (0.4), and the probability that the sperm contains the B allele (0.6) times the probability that the egg contains the A allele. Thus, the probability of AB individuals is (2 × 0.4 × 0.6 = 0.48).

Genotypes of the next generation can be given as shown in the accompanying table.

Allele	Allele Frequency	Genotype	Frequency	Counts for 1000
A (p)	0.6	AA	0.36	360
B (q)	0.4	AB	0.48	480
General formula of HW equation: $p^2+2pq+q^2=1$		BB	0.16	160
		Total	1	1000

The conclusions from HWE are follows:

- Allele frequencies in a population do not change from one generation to the next only as the result of assortment of alleles and zygote formation.
- If the allele frequencies in a gene pool with two alleles are given by p and q, the genotype frequencies is given by p2, 2pq, and q2.
- The HWE principle identifies the forces that can cause evolution.
- If a population is not in HWE, one or more of the five assumptions is being violated. Thus, HWE is based on five assumptions:
  Random selection: When individuals with certain genotypes survive better than others, allele frequencies may change from one generation to the next.
  No mutation: If new alleles are produced by mutation or if alleles mutate at different rates, allele frequencies may change from one generation to the next.
  No migration: Movement of individuals in or out of a population alters allele and genotype frequencies.
  No chance events: Luck plays no role in HWE. Eggs and sperm collide at the same frequencies as the actual frequencies of p and q. When this assumption is violated and by chance some individuals contribute more alleles than others to the next generation, allele frequencies may change. This mechanism of allele change is called genetic drift.
  Individuals select mates at random: If this assumption is violated, allele frequencies do change, but genotype frequencies may.

positional mapping approach based on linkage can cover the entire genome by using a relatively small number of highly polymorphic markers. Standard marker sets for whole-genome linkage scans, based on 200–800 microsatellite polymorphisms, which became available in the 1990s, enabled the successful mapping of hundreds of rare single-gene disorders.

Gene mapping makes use of recombination. The further apart two genes are, the higher the probability of an odd number of crossovers (odd numbers cause recombination), to a maximum of 50% (Figure 12.5). The recombination fraction (the proportion of meioses that result in recombination) is an indication of how far apart two genes are. It can be mathematically transformed into an expected number of crossover events. Distance along a chromosome is expressed in centimorgans. The relation between the length of DNA as measured in base pairs (bp) or centimorgans varies between men and women and from place to place in the genome, but a rule of thumb is that one centimorgan corresponds to about 1 billion bases.

Linkage analysis is carried out only in families with affected relatives and involves genotyping of several markers that spread over the entire genome. Markers that flank the disease gene or mutation tend to highly segregate with disease status in families. Identifying markers within such a segment that consistently accompany the disease may indicate the presence of susceptibility genetic factors near them. However, such factors are neither necessary nor sufficient for the disease to develop.

Linkage analysis can be parametric or nonparametric. Parametric analysis is so-called because it needs a precise assumption about the genetic model with defining multiple parameters. These include the mode of inheritance, gene frequencies, and penetrance. Parametric analysis is often performed on Mendelian traits, in which the genetic model can be easily specified. Complex common diseases, however, are much less tractable, making an advanced assumption impossible. For this reason, nonparametric or model-free linkage analysis is more applicable. In nonparametric analysis, DNA segments identical by descent among affected relatives are examined and analyzed mathematically in terms of the Mendelian probability of inheritance from the defined common ancestor. In the context of common disease, unaffected relatives offer negligible information for linkage analysis because of the low disease penetrance. Segments with excess IBD among affected relatives often harbor susceptibility factors.

12.3.2.1 Identity by Descent

DNA at the same locus on two homologous chromosomes is said to be identical by descent (IBD) if it originated from the same ancestral chromosome (Box 12.5). If two homologous chromosomes from different people are IBD at some locus, the people are related. If two homologous chromosomes from the same person are IBD at some locus, this person is inbred (i.e., has related parents). Two people, neither of whom is inbred, can share DNA IBD at a particular locus on either 0, 1, or 2 chromosomes. Identity by descent is useful for determining similarity between family members. IBD simply measures the amount of genetic material inherited by each offspring from each parent, and compares the two.

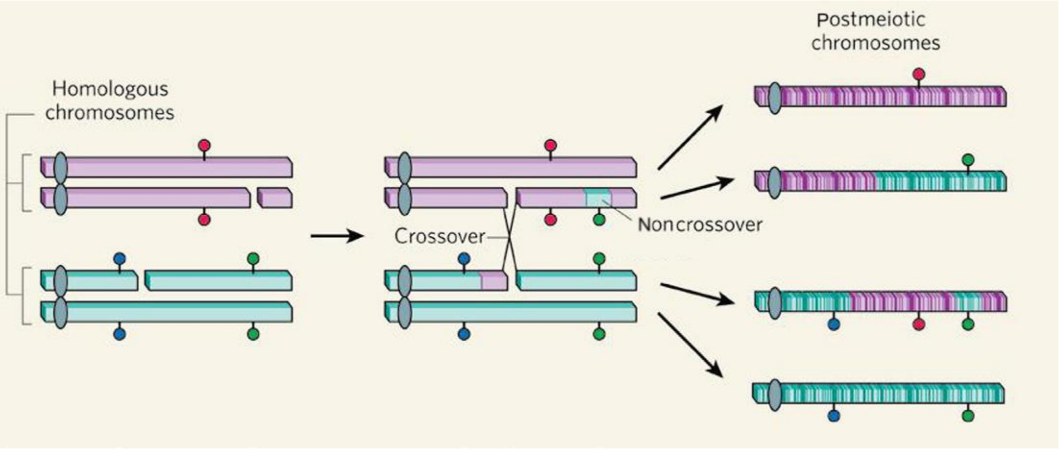


FIGURE 12.5 **Recombination and crossover during meiosis at gamete formation.** During meiosis, a DNA double-strand break is repaired by either crossover or noncrossover recombination, where both mechanisms erase LD. Different genetic markers (red, blue, and green lollipops) can be separated or combined by recombination into different post-meiotic chromosomes. For instance, the association between markers (blue and green) is disrupted by recombination in the second post-meiotic chromosomes because the green marker is no longer associated with the blue marker, whereas the association is conserved in the fourth post-meiotic chromosomes. *Source: From Lichten [35]. Reprinted with permission from Macmillan Publishers Ltd.*

Affected sib pair (ASP) study is one way to conduct a nonparametric linkage analysis. This supposes that if a given marker is co-segregating with a disease-predisposing allele then affected siblings of affected persons are more likely to receive the same allele identical by descent at a closely linked marker locus than if the marker locus was segregating independently (i.e., unlinked) of the disease-predisposing allele. Under the null hypothesis of no linkage, any pair of sibs are expected to share 0, 1, or 2 parental haplotypes with frequencies of 0.25, 0.5, and 0.25, respectively. In other words, according to Mendelian segregation rules, the probability that a pair of siblings share both marker alleles, one marker allele, or no marker alleles, IBD is 0.25, 0.5, and 0.25, respectively (see the accompanying table). However, if the marker is linked to a disease locus, the overall amount of sharing between affected sibs increases. For Mendelian diseases, linkage analysis has successfully identified the major genes and culpable gene variants. For instance, cystic fibrosis is found to be caused by multiple mutations in the CFTR genes. For common complex diseases, however, it has been much less successful. While several factors might explain this failure, the low heritability of most complex diseases and the low penetrance of causal variants are among the most likely reasons [19].

12.4 ASSOCIATION STUDIES

The goal of population association studies is to identify patterns of polymorphisms that vary systematically between individuals with different disease states and can therefore represent the effects of risk-enhancing or protective alleles [18]. This implies that traits are still linked to the surrounding genetic sequence of the original evolutionary ancestor through linkage disequilibrium, or that they are found more often in a given haplotype than outside of it. Association mapping is based on the idea that genetic variants underlying complex traits occur with a relatively high frequency (>1%), have undergone little or no selection in earlier populations, and are likely to date back >100,000 years (the common disease/common variant hypothesis). Association analysis potentially has far greater power than linkage analysis for detecting variants with a modest effect on disease risk, provided that the genetic marker is close enough to exhibit strong linkage disequilibrium (LD) with the functional variant (See Figure 12.6).

A direct association study tests the association between a known functional variant and disease. Indirect association studies are more commonly performed, which tests the association between the disease and a marker locus that lies close to the disease locus and is in LD with it. They may be enhanced by examining multiple markers simultaneously using haplotypes. A haplotype is a linear arrangement of closely linked alleles on the same chromosome that is inherited as a unit. An individual's genotypes at multiple, tightly linked SNPs resolve into two haplotypes, each containing alleles from one parent.

12.4.1 Association Study Designs

12.4.1.1 Candidate-Gene Studies

Candidate-gene studies depend on a set of markers based on *a priori* hypothesis about the role of a selected gene, or a group of pathway-related genes, on a phenotype. The single-gene approach offers the advantage that highly relevant genes can be prioritized and tested first. However, it places a

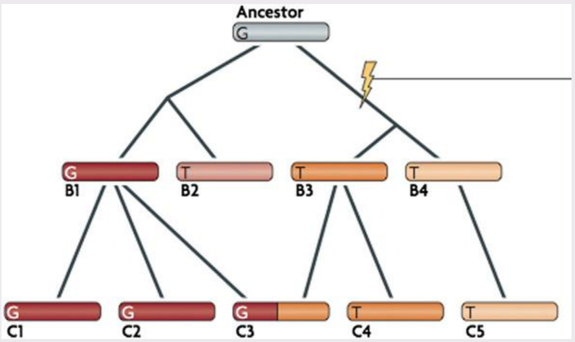
IBD Sharing among Different Relative Pairs

IBD Sharing at Single Locus	Parents	Parent-child	Full Siblings	Grandparent-grandchildren	Uncle-niece	Half Siblings	Identical Twins
Expected probability of 2 alleles, shared IBD	0	0	0.25	0	0	0	1
Expected probability of 1 allele, shared IBD	0	1	0.5	0.5	0.5	0.5	0
Expected probability of 0 alleles, shared IBD	1	0	0.25	0.5	0.5	0.5	0
Proportion of alleles with shared IBD	Exactly 0	Exactly 0.5	On average 0.5	On average 0.25	On average 0.25	On average 0.125	Exactly 1

Note: Assumption: unrelated parents.

BOX 12.5 IBD, IBS, and Coalescence

Here we illustrate the concepts of identity by descent (IBD), identity by state (IBS), and coalescence at a single nucleotide and at a chromosome segment. The accompanying figure depicts an ancestral allele at a locus representing the point of coalescence for alleles in the current population (C1–C5). At the point of coalescence (the most recent common ancestor), this locus carries a copy of a G allele that is subject to a mutation event (G → T; the lightning symbol), leading to a G/T polymorphism. IBD at the polymorphic locus among individuals (C1–C5) can be defined with respect to a base population (B1–B4) in which individuals are assumed to be unrelated (different color chromosome segments in the figure). Then the G alleles in C1, C2, and C3 are IBD to each other because all three descend from the G allele in B1. The T alleles in C4 and C5 are IBS but not IBD because they descend from different alleles in the base population.



Ancestral G allele at a given locus

Mutation event changing the G allele to a T

Base population used for the estimation of IBD coefficients

Current, observed, population of chromosome segments in five individuals

The whole chromosome segments C1 and C2 are IBD because they descend from a common ancestor (B1) without recombination, but chromosome segment C3 is not IBD to C1 and C2.

FIGURE 12.6 **Direct and indirect association.** LD is the key factor in an association study because it induces correlation in short regions of the genome and underlines the susceptibility factors that have been inherited from ancient common ancestors. The d allele is associated with the disease. The a allele, on the other hand, is always associated with the d allele. Thus, an association with the disease can be directly found by genotyping the disease allele d (A), or indirectly found by genotyping the a allele that is in LD with the disease allele (B). Finding the direct association always results in higher association power, but indirect association should result in a significant association when the r^2 of alleles a and d is high and an adequate sample size has been used.

greater burden on the researcher to choose good candidates. The pathway-gene approach involves several candidate genes that together carry out related functions. Examples of pathways are genes related to drug metabolism (pharmacokinetics) or drug response (pharmacodynamics). A primary advantage of the candidate pathway-gene strategy is the ability to identify the effects of an aggregate of genes on a phenotype in circumstances where individual genes have small effects on the downstream phenotype. However, its success is heavily dependent on assumptions underlying the selection of genes to be studied. The risk is that unexpected genes that play an important role in drug pharmacokinetics and pharmacodynamics may remain undiscovered.

In general, experience with candidate-gene studies across all traits has been disappointing. In an extensive review, only 6 out of 166 putative associations were consistently replicated [9,10,20]. The failure of candidate-gene studies to identify the genetic basis of common traits suggests that this approach is subject to several limitations. First, the choice of candidate genes may be inappropriate. Second, the causative genes might be either upstream of the points of action or in the downstream signaling pathways of the selected candidates. Third, the SNPs selected may provide incomplete coverage of all variants in the genes under study. Fourth, most studies are underpowered and encounter problems with population stratification and phenotypic and locus heterogeneity. Finally, candidate-gene studies rely on prior hypotheses about disease mechanisms, which precludes discovery of genetic variants in previously unknown pathways.

The most comprehensive analysis of candidate genes is carried out by resequencing the entire gene in patients and controls and searching for a variant or set of variants that is enriched or depleted in disease cases. Such studies were previously laborious and expensive, and have been largely limited to one or a few candidate genes with sequencing restricted to the coding regions. However, with the advent of next-generation sequencing, whole exome sequencing in which all the coding regions of the genome is sequenced and variants tested for association is becoming more common—though this is technically not a candidate-gene study.

12.4.1.2 *Genome-Wide Association Studies*

Genome-wide association studies (GWAS) offer a hypothesis-free approach that systematically tests hundreds of thousands or more variants in the genome without prior knowledge of the location of the causal variants (Figure 12.7) [19,21]. GWAS are ideal for testing common variants with small effect sizes (Figure 12.8) and thus large sample sizes are required to generate sufficient statistical power. The high number of false-positive results they generate is addressed by stringent multiple testing correction and seeking evidence from multiple replication and validation studies of the top signals. There have been a series of successful GWAS studies of pharmacogenomic traits; these are summarized in Chapter 1.

12.4.2 Population-Based Study Designs

The most popular population-based study design for binary traits (whether focusing on candidate genes, regions, or the entire genome) is the case control study. In a case control study, a set of cases is identified and their genotyping information compared to a set of suitable controls in order to find genetic variants associated with the trait under study. Cases and controls are usually sampled independently from the same ethnic source population. An alternative approach involves sampling from a cohort of individuals that is being followed up prospectively (i.e., nested case control or case cohort study designs), such as provided by large-scale biobanking initiatives.

FIGURE 12.7 **Principles of GWA studies.** (1) Typically GWAS uses a case-control design where the study population is divided into two distinct groups on the basis of phenotype. (2) Samples are genotyped by the GWAS chip, which contains hundred of thousands of markers across the genome. (3) A representative DNA segment from three subjects contains several markers that are typed by the GWAS chip. (4) A cluster plot for signal intensity provides diagnostics for each marker across all samples; the raw data from the genotyping platform is plotted along two axes (one for each allele) to define clusters of data corresponding to the genotype groups. (5) The frequencies of each genotype are compared between cases and controls. (6) The results of the GWAS are represented as genome-wide Manhattan plots, which show the study findings with respect to their genomic position (each color represents a chromosome). The statistical significance threshold differs between studies, but in general signals with $p < 10^{-8}$ are considered significant. *Source: Manhattan plots adapted from McCarthy* [21] *with permission from Macmillan Publishers Ltd.*

For quantitative traits, individuals are either sampled from the two tails of the distribution and their genotyping information is compared similar to a case control study, or they are sampled randomly across the spectrum of trait values in a population; association is investigated by analyzing mean trait values between genotypes categories

12.4.2.1 Tests of Association

For association studies, the genotype effect can be modeled based on mendelian patterns or multiplicative/genotypic models (See Table 12.4). Test of association for continuous traits can be done by linear regression and analysis of variance (ANOVA) statistical methods. Both tests require a

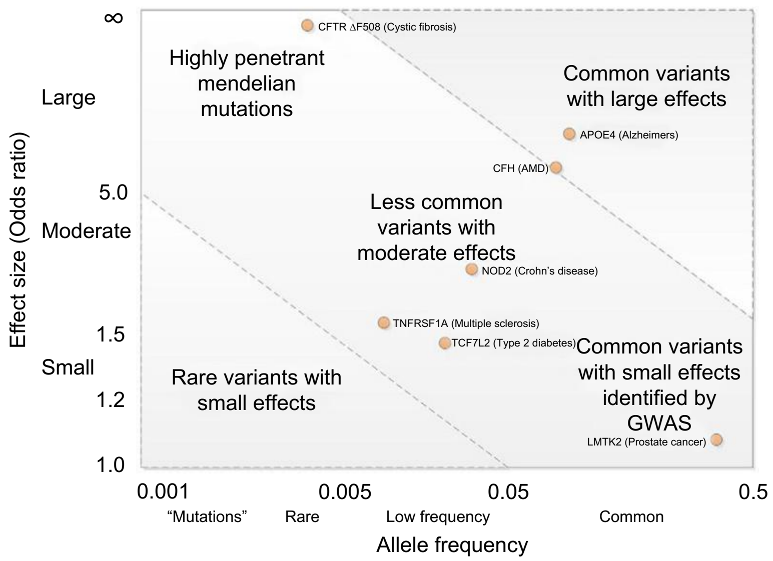

FIGURE 12.8 **Spectrum of allele frequency and effect size in genetic disease.** Rare variants with very large effect size (*upper left*) are the main cause of Mendelian diseases. The common complex diseases are associated with common SNPs with small effect size, which are targeted by GWAS (*lower right*). The bulk of discovered genetic associations lie on the diagonal denoted by the dashed lines. *Source: From Bush and Moore* [17].

TABLE 12.4 Linear Predictors for Genotype Variables Selected Standard Disease Models

Genotype	Model			
	Multiplicative	*Genotypic*	*Recessive*	*Dominant*
a/a	b_0	b_0	b_0	b_0
a/b	b_0+b_1	$b_0+b_1+b_2$	b_0	b_0+b_1
b/b	b_0+2b_1	b_0+2b_1	b_0+b_1	b_0+b_1
Interpretation				
Multiplicatives	b_1 provides an estimate of the log odds ratio for disease risk associated with each additional A allele (also called the haplotype relative risk). If b_1 is significant, there is a multiplicative contribution to disease risk in that the odds ratio for disease risk increases multiplicatively for every additional A allele.			
Genotypic	b_1 and b_2 provide estimates of the log odds ratio for disease risk in individuals with genotypes a/A and A/A, respectively, relative to an individual with genotype a/a. A likelihood ratio test of whether both b_1 and b_2 are significant is equivalent to the conventional 2 d.f. test for association in a 2 × 3 contingency table.			
Recessive	b_1 provides an estimate of the log odds ratio for disease risk in an individual with at least 1 A allele (genotype A/A or a/A) compared with an individual with no A alleles (genotype a/a). A test of whether b_1 is significant corresponds to a 1 d.f. test for association in a 2 × 2 contingency table of disease outcome by genotype classified as A/A or not.			
Dominant	b_1 provides an estimate of the log odds ratio for disease risk in an individual with two A alleles (genotype A/A) compared with an individual with one or two A alleles (genotype a/A or a/a). A test of whether b_1 is significant corresponds to a 1 d.f. test for association in a 2 × 2 contingency table of disease outcome by genotype classified as a/a or not.

normal distribution of the trait. The linear regression analysis assumes a linear relationship between mean value of the trait and genotype with one degree of freedom. On the other hand, ANOVA is performed under the null hypothesis of no association with a general alternative and is analogous to the Pearson two degree-of-freedom test [18]. The genotype–phenotype relationship of quantitative traits can be expressed in a linear dose–response model in which the trait mean of the heterozygote lies midway between the two homozygotes. This model assumes that dominance is absent, and the strength of the genotype–phenotype relationship is expressed using a single parameter with the statistical test of association having one degree of freedom.

Tests of association are usually performed separately for each individual SNP. A biallelic SNP genotype and phenotype are represented in a 2×3 contingency table and a Pearson test (2 df) or a Fisher exact test to test the null hypothesis of no association between the rows and columns. Here, no order or trend of the genotype-phenotype relationship is assumed because each genotype is assumed to associate independently with the trait. This method allows testing of alternative models of association. If the genotype risks are additive, the Pearson test or a Fisher exact test will not be as powerful as tests, such as an allelic test, that are tailored to this scenario. An allelic test is carried out by counting alleles rather than genotypes so that each individual contributes twice to a 2×2 table and then applying a Pearson 1-df test. The allelic test of association is performed under the assumption of HWE in cases and controls combined and does not lead to interpretable risk estimates.

The Cochran-Armitage trend test is similar to the allelic test, but it is more conservative and does not rely on an assumption of HWE. Rather, it tests the hypothesis of zero slope for a line that best fits the three genotypic risk estimates [18]. Adopting the Armitage test implies sacrificing power if the genotypic risks are far from additive, in order to obtain better power for near-additive risks. A different approach is to adopt the Armitage test when the minor-allele frequency is low and the Fisher test when the counts for all three genotypes are high enough for it to have good power for nonadditive models [18].

Relative risk (RR) is a commonly used parameter to express the strength of association and compare disease penetrance among individuals with different genotypes. RR is only applicable for cohort studies where two groups (i.e., exposed and unexposed) can be followed to determine who develops the disease. For case-control studies, odd ratio (OR) is used instead of RR to measure the strength of the association, as it is not possible to make direct estimates of disease penetrance. The value of the OR of a disease is the probability that the disease is present compared with the probability that it is absent in exposed versus unexposed groups.

Although the odds of disease are not directly measurable because of sampling selection, conveniently, it is mathematically equivalent to the exposure OR (i.e., the odds of exposure in cases versus controls), which is easily calculated from exposure frequencies [22]. The allelic OR explains the association between disease and allele by comparing the odds of disease with the A allele to the odds of disease with the B allele. The genotypic ORs describe the association between disease and specific genotype by comparing the odds of disease with one genotype to the odds of disease with another genotype. Typically, two genotypic ORs can be calculated by comparing the two homozygous genotypes (i.e., AA to BB), and comparing the heterozygous genotype to the rare variant homozygous (i.e., AB to BB). The difference between RRs and ORs is very small for a disease with small penetrance. Furthermore, a multivariate statistical method, such as logistic regression, can be performed so that OR includes more SNPs, risk factors, and clinical variables.

12.4.2.2 *Study Power and Coverage*

The power of a genetic association study is its ability to find an association with significant statistical support, in which true findings can be distinguished from chance findings. GWAS power depends on sample size, allele frequency, effect size, and genotype platform coverage [23]. The theoretical expected effect sizes for common variants are for genotypic $RR < 2.0$ (common variants identified by GWA studies have genotypic RR between 1.1 and 1.5). The sample sizes required are further inflated by the large number of hypotheses that are tested in GWA studies, as p-values have to be corrected for multiple-hypothesis testing. Most of the GWA studies so far developed have analyzed variants with $MAF > 5\%$; to detect lower-frequency SNPs even larger sample sizes are required.

Genotyping platform coverage defines the extent of the genetic variation in the human genome that has been represented by markers on the platform [23]. Thus, r^2 represents an important parameter in association analysis because it is inversely proportional to the sample size required for detecting disease association [23]. For instance, if a typed marker is in LD ($r^2 = 0.5$) with untyped functional variants, the effective sample size to identify this association needs to be doubled. Thus, the power is reduced from 90% to less than 40% for a study of 6000 cases and 6000 controls and an MAF of 1%, to obtain a p-value on the order of 10^{-6} [23]. However, it is not reduced when using a marker with ($r^2 = 1$). Conventionally, a value of $r^2 > 0.8$ is considered sufficient for good coverage of untyped variants. This value allows genotyping of a lower number of markers with small losses in power. For a region with several common variants that are in LD, an iterative pairwise comparison can identify the set of tagged SNPs to be included on the platform (the lowest possible number of SNPs that cover the whole region at $r^2 > 0.8$). If the SNPs are in strong LD in this region, the number of tagged SNPs can be decreased by up to 70–80%. However, if they are in a region with low LD, almost every one might have to be genotyped to ensure comprehensive coverage of the region.

Several high-throughput genotyping platforms with different densities and selection methods are currently available: Affymetrix GeneChip, Illumina Infinium BeadChips, Perlegen, and Invader. Currently, marker densities range from 100,000 to more than 1 million per array. Markers are selected using one of four approaches: random selection, “tagging,” a combination of random selection and tagging, and selection of only SNPs with known functions. Arrays include a mixture of genetic variants that are polymorphic in certain populations with different ancestries. Thus, they can be used efficiently in different populations. The choice of genotyping platform is based on sample size, ancestral origin, and marker selection method. Generally, increasing marker densities up to 500,000 increases the study power if the sample size is adequate. However, 1 million–marker arrays are likely to have no great advantage over 500,000–marker arrays, except for African populations, which have lower LD.

A simple way to reduce genotyping costs while retaining power is to perform the study in two or three stages: first, genotype a large number of SNPs in a fraction of samples and then the use of a liberal p-value threshold to find a subset of SNPs with putative associations. Second, genotype the selected subset of SNPs from the first stage in the full sample or a larger one.

12.4.3 Correction for Multiple Testing

The power of association studies is the probability of their rejecting the null hypothesis of no association when the marker is truly associated with phenotype. A type I error is the probability of the null hypothesis being rejected when it is true—that is, a false-positive association between a phenotype and a marker is shown. For a single test, the conventional statistical significance level (α) is 0.05, which means that the probability of rejection of a truly positive null hypothesis is 5%. However, genetic association studies tend to study multiple markers, phenotypes, or the results of multiple genetic models or covariate adjustments [16,18,23]. Consequently, the cumulative probability of making type I errors increases over the entire GWA analysis because of multiple testing issues.

The family-wise error rate (FWER) is the probability of making one or more type I errors in all or part of the hypothesis when performing multiple hypothesis tests. Reducing FWERs decreases the probability of type I errors at the expense of reducing the power to detect truly positive association. In the study design stage, the number of performed statistical comparisons should be considered in order to set a suitable FWER. This means that the association significance level for each marker is corrected for multiple testing to maintain the overall FWER [24]. A correction for multiple testing can be performed using Bonferroni's adjustment, in which the total number of performed test (n) is multiplied by the conventional significance level (α). Another adjustment is Sidak's $(1-(1-\alpha)^{1/n})$. However, both corrections assume that the tests are independent, which is not entirely true because of LD between markers; both corrections are therefore very conservative in the context of correlated tests.

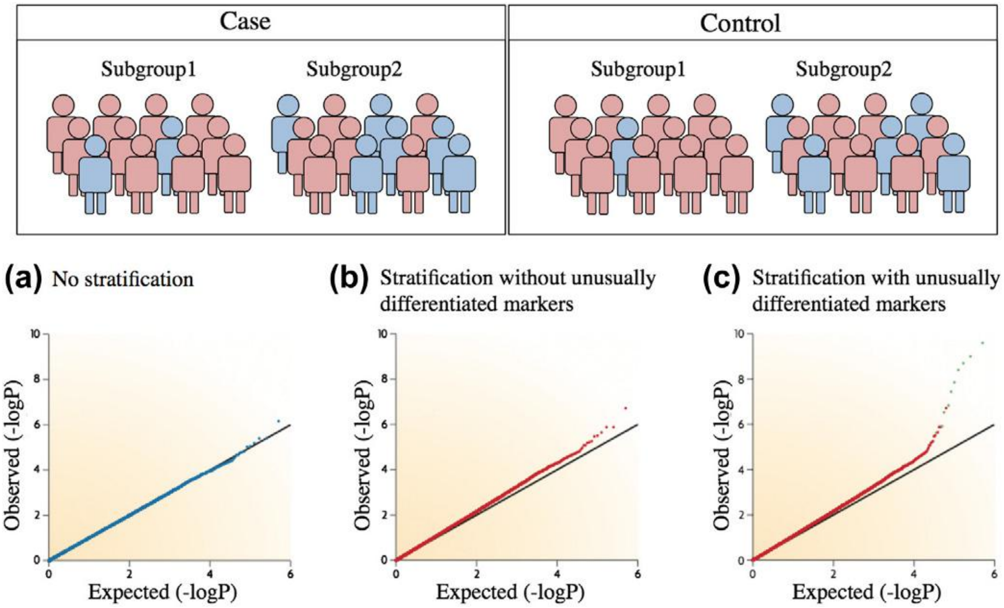
An alternative to FWER is permutation testing, which can be applied in typical association studies that involve huge numbers of tests. It is less conservative than FWER, as it considers the correlation between phenotypes and/or between genotypes. Permutation testing aims to make the null hypothesis correct by randomization; that is, the phenotype of each individual is randomly reassigned to another individual in the dataset and the association p-value is calculated. Hence, the genotype-phenotype correlation is broken except for correlation among genotypes and among phenotypes resulting from LD within an individual. Each reassignment step is repeated a predefined number of times (N) to produce an empirical distribution of p-values, which is then compared with the original p-value from the association test.

For GWAS, strong evidence of association is informally accepted to be below a standard genome-wide significance threshold of 5×10^{-8}. Moreover, plotting the observed p-values against the expected p-values in a quantile-quantile (QQ) plot is a useful for interpreting the GWAS results (Figure 12.9). The QQ plot is a graphical representation of the deviation of the observed p-values from the null hypothesis: the p-values for each SNP are sorted from largest to smallest and plotted against expected values from a theoretical χ^2-distribution. If the observed values correspond to the expected values, all points are on or near the diagonal between the x-axis and the y-axis. If some are clearly more significant than expected under the null hypothesis, points move towards the y-axis. An early separation of the expected from the observed means that many moderately significant p-values are more significant than expected under the null hypothesis. This result is rarely due to thousands of true positives; more often, it is due to population stratification: systematic differences in allele frequencies between subpopulations of the collection of individuals investigated, so that, by chance alone, a large number of p-values are smaller than expected.

12.4.3.1 Population Stratification and Admixture

Confounding by population origin or population stratification is an important and often quoted potential drawback of population-based genetic case control studies. Population stratification arises when (different proportions of) cases and controls are sampled from genetically different underlying populations, thus causing any associations found to be due to sampling differences rather than the disease of interest (Figure 12.9). Confounding occurs when such groups are unequally represented in the study and they differ in SNP allele frequencies and disease prevalence. Consequently, a biased or spurious association will be observed.

Several methods are established to detect and correct for population stratification. During the study design stage, population stratification can be minimized by matching controls to cases based on ethnicity or restricting inclusion to a specific ethnic group. This can be ascertained by



(a) No stratification **(b)** Stratification without unusually differentiated markers **(c)** Stratification with unusually differentiated markers

FIGURE 12.9 **Population stratification.** For a population that contains two subgroups, population stratification occurs when each subgroup has different SNP allele frequencies. The SNPs are thus erroneously associated with case or control status because of the population effect. Here, subgroup 2 has more blue alleles among cases but only because it is more frequent in this subgroup. P-P plots visualize stratification or other confounders. Shown are simulated P-P plots in three scenarios for genome-wide scans with no causal markers: (a) No stratification: p-values fit the expected distribution. (b) stratification without unusually differentiated markers: p-values exhibit modest genome-wide inflation. (c) Stratification with unusually differentiated markers: p-values exhibit modest genome-wide inflation and severe inflation at a small number of markers. *Source: from Price et al.* [26]. *Reprinted with permission from Macmillan Publishers Ltd.*

self-reported ethnicity. Moreover, if the disease prevalence differs between genders, matching based on sex may also reduce stratification.

The most common method used in GWAS is principal component analysis (PCA) using software such as EIGENSTRAT [25,26]. PCA is a multivariate statistical method to dissect and rank the correlation structures of different variables. The principal components (PCs) are calculated so that the first one has the maximum possible variance of its PC scores; this is followed by the second component and so on [25,26]. An alternative method is multidimensional scaling, which is implemented in PLINK but is computationally complex as it requires IBD estimation after merging the study samples with the reference populations. Both methods have to be performed on a large LD-pruned dataset that includes the study's sample and samples with known ancestry from a reference panel such as the HapMap2 or the HapMap3 phase III dataset. During the analysis stage, further correction for any residual subjects can be done by including the principal components as covariates in a logistic regression.

Another method is to use the genomic control to adjust for stratification in the absence of geographical information [26]. Genomic control assumes that the association test statistic is uniformly inflated by a constant factor (λ) and a higher median than expected. The magnitude of λ is estimated by comparing the observed median of a set of markers with their expected median under an assumption of no stratification. Population stratification is assumed to exist if λ has a value greater than 1, which can be corrected by dividing the association test statistic values by λ [13,22]. Genomic control has to be restricted to SNPs that are unrelated to disease status. For instance, in a candidate-gene study λ can be estimated only if the study includes an additional set of markers specifically selected to this purpose. For GWASs, however, the effect of putative SNPs on the estimation of λ is assumed to be negligible.

If geographical information about the study samples is known, then individuals can be classified into subgroups and the Cochran/Mantel-Haenszel test can be used to combine subgroups after separately analyzing them.

12.4.4 Imputation

Genotype imputation is a statistical technique often used to increase the power and resolution of genetic association studies. It works by using haplotype patterns in a reference panel to predict unobserved genotypes in a study dataset [27]. Imputation is typically used when combining data from genotyping platforms with different SNP contents. For instance, only 250,000 SNPs are shared by the Affymetrix SNP 6.0 and Illumina Human 1M arrays [28]. In combining the output of these two arrays to generate a new dataset with higher coverage, imputation reduces the batch effects and reduces direct genotyping costs. Several imputation methods are available [27]. A popular one uses a variant of the expectation maximization algorithm—an iterative frequentist method of maximizing the likelihood of the imputed variant. Basically, random variants are selected to fill the missing genotype, and the likelihood of observing this selection is examined. Then the imputed values are sequentially corrected over 10–100 iterations until the estimated error is minimized. The algorithm has to be run many times with different initial states to provide certainty, as it can get caught in a local maximum (providing a false impression of the best solution). An alternative is to use fitted Bayesian models using Markov chain Monte Carlo (MCMC) algorithms, which are iterative and explore the entire model space, not just the maximum.

12.4.5 Validation and Replication

Independent replication represents the sine qua non for reliably claiming a true genetic association [29]. A "true replication" indicates the evaluation of statistically significant association signals in additional independent study samples. Such replication efforts aim at reproducing the association signal identified in the initial study in nonoverlapping study samples, and will typically involve the same genetic variant, or a variant with very similar or identical statistical properties (a "proxy") as defined by a high correlation coefficient (r^2).

"Technical validation," conversely, indicates the reanalysis of all, or a subset of, genetic variants investigated in the association study and is carried out on the original study samples, often using a different genotyping platform. The aim of technical validation is to detect errors in genotyping or genotype imputation that could lead to differential genotype calling and spurious associations.

Evidence for "indirect replication" can be claimed when the replication study involves either a different allele at the same locus (e.g., different genetic variants or haplotypes in the same genomic region) or a phenotype trait that is closely correlated, but not identical to, the original study trait (e.g., an association with total cholesterol at a locus previously identified as associated with LDL cholesterol). While indirect replication can provide confirmatory evidence for the implication of a genetic locus in determining one or more traits, alone it does not provide sufficient evidence of replication of findings. However, often indirect replications can be important to gain additional insights into either the allelic architecture of a locus of interest, or of shared or unique genetic determinants of correlated biological traits or processes.

Failure to replicate the association signals on populations with different ancestries does not necessarily invalidate the initial findings. The differences in LD pattern across different populations can be used to narrow the region of interest for later genetic and, possibly, functional analysis [29]. An important factor to consider in a replication study is distinguishing between tests of the same SNPs as in the original study—those in strong LD with the reported SNP and others in the reported region—in order to search for additional variants association with the phenotype. For instance, a marker that is not in strong LD with a causal variant might be identified in a study; testing it in a different population might lead to false refutation of the association, but testing additional markers in the same region might reveal another association signal. Inclusion of new SNPs should be clearly rationalized by separating them from the other, previously tested SNPs. If the new SNPs are selected on the basis of LD patterns across populations with original SNPs, the different patterns should be empirically confirmed in the two populations—original and replication populations [29].

12.4.6 Meta-Analysis

Individual studies usually do not have enough power to detect variants with small effects due to small sample sizes. One way to increase power is by joint analysis (meta-analysis) of data from comparable GWA studies. Meta-analysis is used either for discovery of new variants or for replication of previous findings. Discovery analyses usually look across the whole genome, while replication analyses concentrate on a limited number of prespecified variants [30,31].

For the discovery meta-analysis, two designs are commonly used. The first is a consortium meta-analysis in which several partner research groups conduct GWA studies for the same phenotype. Each group follows the same criteria of quality control and primary analysis method. The groups can further collaborate to follow up any putative association signals. The second design involves combining the results of primary GWA studies with a publicly available GWAS data to increase study power. Typically, this design uses data from fewer primary studies that were initially intended to be independent but, because of the lack of power, were combined with other GWA studies. For this reason, difficulties can be encountered because of differences in quality control and method of analysis.

Replication meta-analysis studies aim to confirm previous findings as well as provide effect estimates that are free from self-reporting bias. A previously identified association's failure to be replicated may point to unsuspected interactions or, with some studies, methodological issues.

12.4.7 Fine Mapping and Resequencing

The ultimate goal of GWAS is to reveal functional variants underlying validated association signals and to characterize their effects. The confirmed signals that have passed all the discovery and replication stages indicate only statistical association. Furthermore, the typed markers are usually found in large LD blocks that may contain several genes, making it difficult to identify the causal gene. This scenario is even more complicated by the fact that many complex traits' susceptibility effects are mediated through remote regulatory elements, where the coding exon of the susceptibility gene might lie well beyond the interval of maximal association [21]. For these reasons, translating the confirmed association signals into an ordered list of candidate functional variants at a given locus is challenging. One way to identify functional variants is to perform fine mapping of the associated locus followed by deep resequencing of the association region. Candidate variants can then be prioritized by several bioinformatics and genomic methods to select a subset for further experimental study.

Fine-mapping approaches indicate a comprehensive exploration of variation around strong signals of association through additional genotyping and/or resequencing [32]. In fine mapping, additional genetic variants in regions of association are identified from sequence variant repositories (e.g., dbSNP, HapMap, 1000 Genomes project, www.1000genomes.org) or through targeted resequencing of association intervals (defined by recombination hotspot boundaries) in a subset of individuals to compile exhaustive catalogs of genetic variants within associated intervals. These variants are then statistically evaluated to distinguish between the true functional variants from other variants that are in LD with it. Selecting variants for fine mapping can sometimes be targeted more toward variants with particular aspects such as those with particularly strong biological credentials or those previously examined by expression studies [21]. This can facilitate the identification of true functional variants and confirm the implicated molecular mechanisms. In the absence of such clues, targeted resequencing is needed to examine the locus. Resequencing is also useful in identifying rare variants that are beyond the reach of typical GWA studies.

Targeted resequencing allows a comprehensive inventory of genetic variants within the targeted regions, leading to their systematic fine mapping. The objectives of resequencing have to be explicitly stated in order to formulate a study plan, which has to consider several factors: defining the ratio of reference samples, such as individuals from the HapMap panel, to cases, and determining if cases will be selected on the basis of carrying the known susceptible variant or haplotype; defining the extent of resequencing to be undertaken that will have an impact on the allele spectrum recovered; and, finally, determining if the resequencing will search for rare variants while acknowledging the difficulties in obtaining robust statistical evidence for rare variants in unannotated sequences [21].

12.4.8 Reporting of GWA Studies

Any report of GWA study results should include a detailed description of the study design, genotyping procedure and platforms, quality control procedures and thresholds, statistical methods and calculations, and results. Examples can be found in published papers or even as online supplements. A checklist containing key information that should be included in any GWA study report was recently published [29,33]. A checklist is necessary because the number of published GWA studies is steadily increasing, with wide variability in reporting and in the quality of their empirical findings, which may obscure their strengths and weaknesses. This in turn will have an impact on the scientific and clinical relevance of their results, in particular within the framework of systemic reviews and meta-analysis [29,33].

12.5 CONCLUSIONS

This chapter has provided an overview of the principles of determining the genetic basis of a phenotype. While the principles remain the same, technological advances during the last decade have revolutionized DNA sequencing. Next-generation sequencing generates huge amounts of data, which poses a challenge both for data storage and analysis; consequently, it often necessitates the use of powerful computing facilities and efficient algorithms. The three common applications of next-generation sequencing are (1) variant detection to identify genetic differences between two samples; (2) RNA-seq to determine the expression level of genes, as well as discover novel transcripts; and (3) ChIP-seq, which is a method of screening protein-DNA interactions. The analytic methods for these technologies are rapidly evolving and describing them is beyond the scope of this book.

13.1 OVERVIEW

Progress in pharmacogenomics has accelerated rapidly in the past decade, driven for the most part by technological developments in molecular medicine. The next decade will see pharmacogenomics driven by sequencing as well as by collection of, linkage between, and access to increasing amounts of molecular and phenotypic patient data. There is clear evidence, especially from oncology, that the development of molecular understanding of drug response—in parallel with a medical informatics system that allows observation of linkages between clinical presentation and biomarker status using large datasets to accelerate predictive biomarker discovery—is of vital importance to the success of a targeted therapeutic.

The recognition that drug target biology may be extremely complex is important for appropriate biomarker identification. The key bottleneck is data analysis in the molecular (bioinformatics) and clinical (medical informatics) realms. Bioinformatics is at the intersection of molecular biology, computing, and statistics, and its main challenges are data storage and data analysis. The most common type of data are DNA, RNA, and protein sequences. This chapter provides an introductory overview of the field of bioinformatics.

To compare them, sequences must first be aligned, which may involve determination of a scoring metric and

penalties for gaps. When working with a large amount of data, finding an optimal multiple-sequence alignment is described as NP-complete, so we require "heuristic" methods as alternatives to exact methods. Phylogenetics uses the similarities/differences between sequences to infer relationships, and helps us better study evolution. Protein modeling may also make use of multiple-sequence alignments to infer the structure of proteins with an unknown conformation. For example, a sequence of unknown structure may be mapped to one of known structure and adjusted in regions where the sequence is different and chemically unlikely to form the same structure. Sequence analysis, phylogenetics, and protein modeling are related in many respects and have long been regarded as bioinformatics fields [1].

Because of recent developments in technology, a multitude of high-throughput techniques are now in common use. These techniques gather "omics" datasets, often used to screen for biomarkers or identify pathways that appear to be affected by a disease state. New methods have been developed for their analysis (described in other chapters), specific to proteomics, metabolomics, and so on. A great deal of these newly gathered data have been added to existing databases, and new databases have been created to accommodate new types of data.

This chapter describes some key concepts and methods in areas traditionally thought of as bioinformatics and discusses several useful databases. It includes a brief background and a discussion of the difficulties with data storage and continual database growth. Finally, file types common to IT and bioinformatics are described and contrasted to familiarize the reader with the files they should expect to work with and to provide an understanding of the utility of an appropriate file structure.

13.2 ANALYSIS OF SEQUENCES OF NUCLEIC ACIDS AND PROTEINS

This section considers some of the common types of computational analysis one is likely to perform on a newly obtained nucleic acid sequence and on the protein sequence(s) resulting from its conceptual translation. Our discussion is restricted to different types of sequence comparisons, although identification of simple motifs (including codons), being regarded as the most minimal type of comparison, is included. Other forms of analysis, such as secondary and tertiary structure and physical properties, fall outside the scope of this section, as does the analysis of large genomic regions.

Before discussing sequence comparisons, it is pertinent to reflect on the metrics of comparison. Although this is trivial in the case of tasks requiring perfect matches (e.g., finding restriction endonuclease recognition sites in a DNA sequence), determining the best alignment of two (or more) similar but nonidentical sequences, say, involves quantifying similarities and differences.

In comparing two nucleic acid sequences, it might be reasonable to score 1 for a match and 0 for a mismatch between nucleotide bases, but such a simplistic approach is unsatisfactory for protein sequences. Experimental analysis shows that in the corresponding positions of closely related proteins certain amino acid changes are more common than others, which is understandable both in terms of the physicochemical requirements for amino acids in the three-dimensional structure of proteins (and in their function) and in terms of the different number of mutations that may be required to interconvert different amino acids. This latter consideration also implies that the scoring system one uses should take into account the time since the two sequences under comparison diverged from a common ancestor. Amino acid comparison matrices are available for different degrees of divergence, the BLOSSUM matrices [2] being in most common use today. Users should check that the default matrix used by a program is the most suitable one for the evolutionary distance between the sequences being compared (Figure 13.1).

In cases where a program presents a "best" sequence alignment, it is generally necessary to introduce gaps in it at positions where deletion or insertion mutations are presumed to have occurred. However, to prevent an unrealistic number of gaps, programs exact penalties for their introduction, so they are inserted only if the penalty is compensated for by the additional scoring matches it produces. Users should be aware that gap penalties may be varied, and that default values, although perhaps appropriate in most cases, may not be suitable for all situations (e.g., the ends of incomplete sequences).

In many cases there are a variety of programs, both commercial and free, that perform the comparisons to be discussed. Rather than trying to produce a list, we will refer primarily to programs of the open-source EMBOSS package [3], which can be either downloaded from http://emboss.sourceforge.net/ and run on the user's own computer (albeit primarily on the command line), or used on the web pages of EBI, the European Bioinformatics Institute (www.ebi.ac.uk/Tools/emboss/).

We will mention the general utility and limitations of programs in each category, but one aspect of the latter needs to be explained for the benefit of readers without a background in informatics. In writing software to solve a problem such as sequence alignment, the programmer tries to devise a logical procedure (algorithm) for achieving this and then implements it in computer code. The time it takes the coded program to run is related to the number of key operations, n, and generally in sequence comparison the more nucleotides or amino acids in a sequence, the more key operations have to be performed. What is important to realize is that the mathematical nature of the relationship between n and

FIGURE 13.1 **BLOSSUM62 amino acid substitution matrix.** The central diagonal is shaded to emphasize how the score for a perfect match varies with amino acid. The "62" in the matrix name indicates that it was constructed from blocks with 62% identity. For evolutionary distant sequences, matrices constructed from blocks with lower identity, such as BLOSSUM45, are available.

the time a program takes to run varies depending on the algorithm: the time complexity (as it is called) can be on the order of logn, n, nlogn, n^2, n^3, 2^n, and so on.

The order of the time complexity is generally of much more importance than the length of the sequence, although the latter can sometimes be relevant. This means that there are situations in which there is a mathematically sound algorithm for solving a problem, but it would take an eternity to run. The threshold of practicality occurs at a time complexity of the order of n^2, and above this programs adopt algorithms employing what are called heuristics. This is an approach in which certain simplifying assumptions are made on the basis of what is usually the case (the "rule of thumb") to achieve an answer that is likely, but not certain, to be correct in a reasonable time. The user of sequence comparison programs employing this approach should be aware of this limitation, especially when interpreting unexpected results.

13.2.1 Analysis of Sequences for Small Motifs

The simplest type of sequence comparison is employed in the identification of small motifs such as restriction endonuclease recognition sites. The comparisons involved are exact, so no scoring system is involved, and the number of comparisons is of the order of the length of the sequence so that the program can run quickly. Even when a set of comparisons has to be made, in the case of searches for motifs, such as promoters with consensus sequences, time of execution is not a problem. A range of such programs is available in the EMBOSS package mentioned earlier.

A more sophisticated type of query involves searching a sequence for a pattern: a combination of motifs (either precise or consensus) with additional fuzzy features, such as that the distance between them falls within a range. This sort of pattern specification can be represented in a notation termed a "regular expression" in computing science, and processing methods for it exist in many computing languages, most notably Perl. For those without the requisite skills to write and use regular expressions, there are web facilities such as Prosite (http://prosite.expasy.org/scanprosite/) where one can enter a pattern in response to simple instructions, generating a regular expression that the underlying software uses to analyze the sequence of interest.

13.2.2 Comparison and Alignment of Two Sequences

It is often necessary to compare a sequence of interest (the query) with a second sequence that is believed to be related, in order to obtain the best detailed alignment of the two. This involves matching amino acid with amino acid (or base with base) and introducing gaps where appropriate, as illustrated in Figure 13.2(a). As this requires determination of the highest-scoring alignment from a huge number of

FIGURE 13.2 **Different sequence comparisons illustrated for various examples of isocitrate dehydrogenase.** (a) Global alignment using the program Needle. The two amino acid sequences labeled "AAA2406" and "AAH21967" are of *Escherichia coli* ICDH and Human ICDH 3α, respectively. Identical amino acids are indicated by vertical bars, related amino acids by a double dot, and unrelated amino acids by a single dot. (b) Dot-matrix comparison using the program Dotmatcher. The sequences are as in (a). (c) Multiple-sequence alignment using the program ClustalX. Various human isoforms of ICDH are compared with ICDH from *E. coli.* Similar amino acids are highlighted by color; identical amino acids by an asterisk. The height of each bar corresponds to the number of identical amino acids at that particular position. (A final small section of the comparison is omitted for reasons of space.)

possibilities, at first sight it appears to fall into the category of problems that cannot be solved in a finite time. However, a sophisticated computational approach called dynamic programming allows the problem to be reduced to the generation of a two-dimensional (2D) matrix of pointers, the path through which represents the sequence alignment. This gives a time complexity on the order of n^2, which, although not ideal, allows sequences of up to 1000 or so amino acids to be aligned in a reasonable time.

The original application of dynamic programming to the complete alignment of sequences (global alignment) is due to Needleman and Wunsch [4], with a variant by Smith and Waterman [5] to allow only the most related regions to be aligned (local alignment). The EMBOSS implementation of these algorithms is entitled *Needle* or *Water*, respectively. A comparison matrix is used in the scoring system of these programs, as well as gap penalties of a little more complexity than previously indicated. Because insertion and deletion mutations often involve several amino acids, it is reasonable in determining gap penalties to distinguish between the creation of a new gap and its extension, the latter usually incurring a much smaller penalty than the former.

It is important to realize that it is not cheating to alter the penalties, or even to customize the comparison matrix. Default values are only the product of general biological experience and are not intrinsic to the algorithmic logic. If one has specific biological knowledge that can inform a particular sequence comparison, it is perverse not to use it (and, of course, report that one has done so). For example, if it is known that certain residues in a sequence should align because they represent, say, active site residues in an enzyme, it is perfectly reasonable to force their alignment. This can be done by modifying the comparison matrix to accommodate an unused symbol, "Z," assigning a high score to a perfect match with it, and replacing the residues to be aligned in the sequence with "Z."

One other feature of such alignments should be noted. It is possible for there to be more than one alignment of two sequences with the same score, although only one is presented in the output.

13.2.3 Dot Matrix Comparison of Two Sequences

Sometimes the object of comparing two sequences is not to obtain a base-by-base or amino acid-by-amino acid alignment, but to get an overall view of regions of similarity and difference. In such cases, dot-matrix comparison can be useful. The principle here is to place the two sequences on the axes of a 2D grid and draw imaginary lines horizontally and vertically back from each grid cell to the axes. If the two bases (or amino acids) at the points of intersection on the axes are identical, a dot is placed in the grid cell. For regions of high identity, the eye will see the dots as a continuous diagonal line, interrupted by insertions or deletions in one of the sequences (Figure 13.2(b)). The time complexity of this can readily be seen to be of the order of n^2.

In practice, a more sophisticated approach is adopted to determine whether a dot should be drawn at a particular position, so as to avoid a large amount of random noise in some cases (there is always a 1-in-4 chance of a match with nucleic acid sequences) or a signal too low to display similarities in other cases (e.g., diverged proteins). What programs such as Dotmatcher in the EMBOSS suite do is compare not a single base or amino acid but a short sequence window (longer for a nucleic acid sequence than for a protein sequence) and specify a threshold—a percentage of the maximum possible score—above which a dot should be drawn. In the case of proteins, a scoring matrix is used to determine the score. The importance of varying window and threshold values in this sort of program cannot be overemphasized—individual comparisons differ so much that default values frequently result in suboptimal signal-to-noise ratios.

It should be pointed out that, although dot matrix comparison is useful for revealing insertions and deletions (and for revealing intron positions in comparisons of genomic and cDNA sequences), gap penalties do not feature in the scoring system. All the program does is calculate whether or not to draw a dot—interpretation in terms of gaps and horizontal lines is done by the user when inspecting the resulting graph.

Dot-matrix comparisons may also be used to identify repeats within a single sequence. If a sequence is compared to itself, in addition to the uninterrupted diagonal line of self-identity across the matrix, any direct repeats within it are seen as additional short diagonals, displaced to either side of the main diagonal. Similarly, if a nucleic acid sequence is compared with its inverse complement, any inverted repeats appear as short diagonals, generally lying off the position where a central diagonal is. (This can be seen if one considers a dot matrix comparison between a sequence 5′-TTAAGCxxxGCTTAAxxx-3′ and its inverse complement, 5′-xxxTTAAGCxxxGCTTAA-3′.)

13.2.4 Multiple Sequence Alignment

We have discussed the problem of alignment of two sequences and its solution by dynamic programming. What happens when we want to find the best alignment between a group of related sequences? Unfortunately, although dynamic programming can, in theory, find the best alignment, the time complexity is n^x, where x is the number of sequences to be compared. For $x = 3$ this is just about feasible if one is in no hurry; for more than three sequences, dynamic programming is not viable.

Because of this, heuristics are employed in the programs currently in use, one of which, Clustal [6], we consider here (Figure 13.2(c)). At the time of writing, ClustalX is the latest version that can be downloaded from www.clustal.org/, although a more advanced version can be used online at the EBI website (www.ebi.ac.uk/Tools/msa/clustalo/). Another popular program, not discussed here, is T-coffee, available at www.tcoffee.org/ [7].

Clustal's heuristics have evolved over time, but it is useful to consider one aspect of them here. The assumption made is that regions of similarity between the most closely related sequences are also represented in the multiple alignment (albeit interrupted by gaps), and that it is valid to use the alignment of these sequences as a nucleus from which to build the multiple alignment. Initially a series of all possible pairwise alignments is performed, generating a guide tree of the similarities between the sequences. The highest scoring alignment is presumed to represent the similarity between the two most related sequences and is used as the starting point.

The preliminary alignments use a standard amino acid–scoring matrix (see Figure 13.1), but subsequent comparisons use dynamically generated position-specific matrices based on the alignment's current state at any time. Consider, for example, the initial alignment of two sequences in which at position x a D (aspartic acid) is aligned with an E (glutamic acid), whereas at position *y* a D is aligned with another D. The revised scoring matrix used to align the sequence most closely related to the first two (as determined by the guide tree) assigns a lower score for matching a D to position x than for matching it to position y, and indeed the score for a match at position y is higher than in the original standard scoring matrix. Conversely, the score for aligning an E at position *y* is lower than in the original scoring matrix.

There are a number of problems with this approach, which have been the stimulus for continual improvements in the program. One problem is that the alignment can easily be biased if there are several very similar sequences. Another is that an initial gap insertion, which can clearly be seen to be erroneous after other sequences have been added, becomes set in stone. A similar sort of problem occurs where related proteins have core regions of similarity but very different N- or C-terminal sequences. After an initial run, users may therefore have to remove certain sequences or remove, say, the N-terminal regions of all sequences in order to obtain a satisfactory multiple-sequence alignment.

13.2.5 Database Searching

After obtaining a new sequence, one frequently wishes to know whether it is related to any previously determined sequences. This involves successive pairwise comparisons with sequences in a database. Although the time complexity of an individual comparison may only be n^2, the number of sequences in the publicly accessible GenBank (www.ncbi.nlm.nih.gov/genbank/) currently exceeds 100 million. Thus, a heuristic approach is needed to search this completely.

The premier program (or suite of programs) for this purpose is BLAST [8], which is most frequently used on the NCBI website (http://blast.ncbi.nlm.nih.gov/), although it can be downloaded and installed locally by those with the appropriate technical expertise. BLAST is continually evolving and employs a variety of devices. For this reason, we mention only one aspect of the heuristic approaches it uses. The assumption made is that any good alignment between the query and the target sequences contains short high-scoring ungapped matching regions (segments).

The program starts by indexing the segments in the query sequence, which allows rapid identification of any small high-scoring diagonal segments in the comparison (a BLOSSUM scoring matrix is used for proteins). It then determines whether these can be extended diagonally to encompass other such segments. If the search is unsuccessful, it is abandoned and the next sequence is considered. Time is allocated only to more extensive comparison of the highest-scoring target sequences of the initial sweep.

The output from BLAST shows a pairwise dynamic programming alignment with the highest-scoring targets, and this generally includes gaps. However, it should be stressed that the heuristic described allows BLAST to look for related sequences only on the basis of ungapped regions of similarity. This was the situation in initial versions of BLAST, although a "gapped BLAST" has been introduced.

A variant of BLAST, PSI-BLAST [9], performs "profile searching." Rather than searching with a single-query sequence, GenBank is searched with a profile derived from a family of similar sequences in order to discover additional, perhaps more distantly related, members of the same family. This is similar to multiple-sequence alignment, where the final scoring matrix used to make a multiple alignment can be considered as the scoring matrix for a profile of aligned sequences.

The beauty of the BLAST web interface is that it is extremely clean and simple to use. A query sequence can be dropped into a form field, a button pressed, and a result generally obtained within a minute. However, many additional options are available if this simple approach produces unsatisfactory results, and the website contains clear and extensive information about BLAST, which must be the most widely used bioinformatics program on the Internet.

13.3 MOLECULAR EVOLUTION AND PHYLOGENETICS

Molecular evolution is the study of the evolution of certain biological macromolecules: DNA, RNA, and proteins. The two primary phenomena assessed are the rate of change over generations and the pattern of the differences between or within specific organisms. The changes that occur can be point mutations (substitution and deletion or insertion of a single base) or large events such as inversions, translocations, and larger insertions/deletions. Studying molecular evolution allows us to discern mechanisms for evolutionary changes and to reconstruct evolutionary history.

Bearing in mind the "central dogma" of molecular biology, that *DNA makes RNA makes protein* [10], it might seem redundant to mention all three of these macromolecules in our definition of molecular evolution, however, it should be noted that many viruses have RNA as their genetic material and, in fact, their replication has a particularly high rate of mutation: between 10^{-3} and 10^{-5} per base per generation [11]. If genetic changes do not result in a codon that codes for a different amino acid, the mutation is said to be *silent*. For some purposes, then, it may be more prudent to compare amino acid sequences rather than genetic sequences.

To make the distinction between change within and between organisms, it is important to introduce the concepts of homology, orthology, and paralogy. Homologous sequences share an ancestry and have deviated from each other by either a speciation event (orthology) or a gene duplication event (paralogy). Homology is *inferred from observations of similarity*, but is distinct from similarity

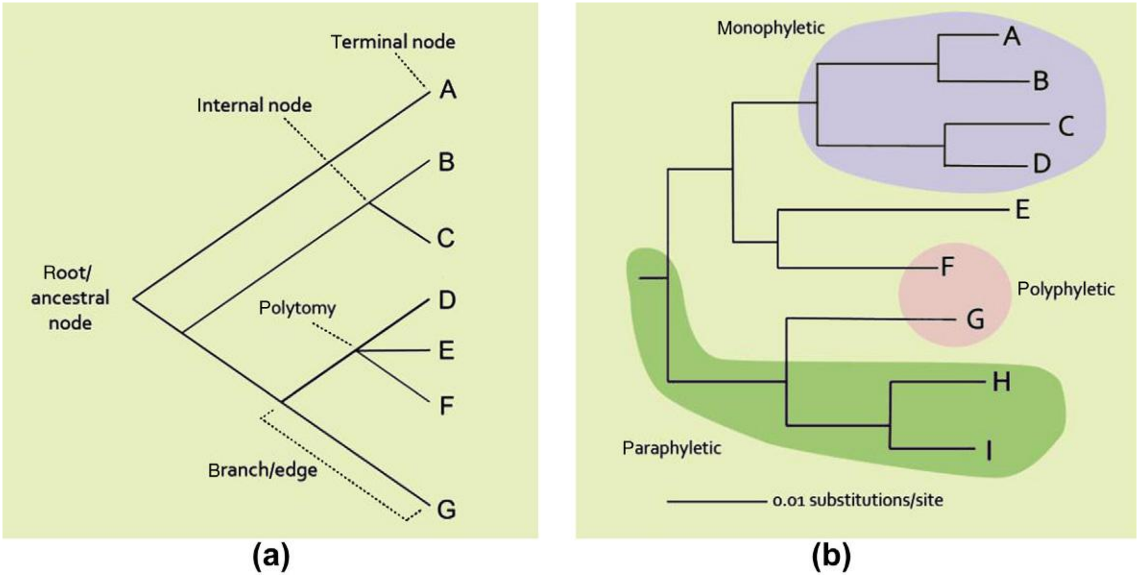

FIGURE 13.3 **Phylogenetic relationships using various types of tree.** (a) Common features of a cladogram. The terminal nodes A–G are the sequences used to infer the organization of the tree itself and to infer internal nodes. The root of the tree is the node that is ancestral to all others. The polytomy node has a degree of >3 (i.e., it relates directly to four or more other nodes). Note that branches are also called edges and nodes are also called vertices. (b) Monophyletic, polyphyletic, and paraphyletic groups. Monophyletic groups (clades) must by definition include all child nodes of any of its members. Paraphyletic groups, in contrast, must contain all ancestors of all nodes in the group but not all child nodes. Polyphyletic groups are composed of unrelated nodes descended from more than one ancestor. *Source: Hand-drawn by Emma Fitzgibbon based on example provided by author.*

in that the sequences must be related *by descent*. Often the term *homology* is used either as a synonym for similarity or with the assumption that it is necessarily implied by similarity, although strictly speaking this is not the case. Sequences can be similar but not homologous as a result of convergent evolution, and they can be dissimilar yet homologous, although this is more difficult to ascertain.

Phylogenetics deals with identifying evolutionary relationships between organisms or between genes. In the case of the evolutionary relationships between organisms, this is also often known as "phylogenetic systematics." Using molecular rather than morphological data has revolutionized systematics, from redefining our place among the primates [12] to allowing us to analyze the evolution of viruses and even revealing archaea, an entirely new domain of life [13]. Phylogenetics is also extremely useful in understanding the spread of contagious disease [14] and the evolution of the responsible pathogens [15].

13.3.1 Tree Terminology

Multiple sequence alignments, as explained in Section 13.2.4, help identify homology and reconstruct evolutionary history. Alternatively, it can be said that variation between sequences is used to infer phylogeny. We depict phylogenetic relationships using various types of trees (Figure 13.3). Evolutionary trees are graphs consisting of nodes and branches, which in mathematics are often referred to as vertices and edges. Trees may be either rooted or unrooted, where the root is a node that depicts an ancestor common to all of the other nodes in the graph. Intuitively, then, rooted trees depict directionality in evolution, whereas unrooted trees merely show evolutionary distances. Rooted trees are commonly drawn with the root on the left and the terminal nodes (or tips)—for which we have sequence data—on the right. In between the root and the terminal nodes, there may be internal nodes that depict hypothetical genes or organisms—for which we have no experimental data.

The lengths of the lines that constitute the branches can mean different things depending on the type of tree. Cladograms (Figure 13.3(a)) show only the orders of branching; the lengths of the branches are meaningless. In phylograms (as shown in Figure 13.3(b) and also known as additive trees), the horizontal branch lengths correspond to evolutionary changes whereas the vertical distances are meaningless and only used for separation and clarity. Ultrametric trees (also known as dendrograms) are similar to phylograms, but the root must be equidistant to each terminal node. In this case, the distance represents either actual time or "time" on a molecular clock. The concept of a molecular clock is that sequences evolve at an approximately constant rate, and so the genetic difference between two species or genes is proportional to the amount of time since the speciation or gene duplication event. It should be noted, however, that there is no one universal molecular clock—differences between genomes of different species, and throughout different genomic regions of the same species, lead to different rates of mutation/evolution.

It is often useful to describe groups of nodes and how they relate to one another. Clades are groups of nodes united by ancestry, in which every descendant of every node is present; in other words, a clade is an entire branch. This must not be confused with grades, which are nodes grouped by characteristics such as morphology. Clades are also described as monophyletic groups. Two concepts that contrast with monophyly are paraphyly and polyphyly (Figure 13.3(b)). Paraphyletic groups are made up of consecutive nodes that share common ancestry but in which not all descendents of all nodes are present. Polyphyletic groups do not include a common ancestor of all of its members. An alternative to cladistic classification is phenetic classification, which is based on overall sequence similarity rather than ancestry. Phenetic classification particularly causes different classifications when different rates of evolution occur in different branches of the tree.

Tree diagrams represent genes, species, or both. They therefore can describe paralogy, orthology, or the two of them. In other words, depending on the type of information in the diagram, a branching can represent either a gene duplication event or a speciation event. Trees are similar to hanging mobiles (as in kinetic art) in that the branches can be rotated without altering the meaning of the tree or the relationships between terminal nodes. The specific order in which the terminal nodes are represented is merely stylistic and not inherently meaningful.

Trees allow us to distinguish between ancestral and "derived" (newly and separately occurring) character states or sequence variations. A plesiomorphy is an ancestral character state, whereas an apomorphy is a derived state. If an apomorphy occurs in one sequence only, it is described as autapomorphic, whereas if it occurs in several sequences it is described as synapomorphic. Homology describes two identical character states in multiple terminal nodes inherited from a common ancestor. In contrast, homoplasy describes two identical character states in multiple terminal nodes that have occurred independently.

The degree of a node is the number of branches that are connected to it. A tree is said to be fully resolved if the root has only two children and none of the internal nodes has a degree of more than three—that is, one parent node (ancestor) and two child nodes (descendants). A node having a greater degree than this is described as a polytomy (Figure 13.3(a)). If a tree has no polytomies, it is said to be fully resolved, whereas a tree completely unresolved is said to be a "star tree." Polytomies are described as "hard" if they indicate events of simultaneous divergence for all descendants involved. They may be described as "soft" if they represent an uncertainty in the order of divergence. Other related terms here are bifurcation (divergence into two branches) and trifurcation (divergence into three sequences).

13.3.2 Principles of Tree Inference

Alignments of terminal node sequences are used to make inferences about the relationship of the nodes and about the inferred ancestral nodes for which there are no data. Different parts of the genome are subject to different mutation rates because of factors such as GC content or the presence of CpG islands [16]. Genetic changes are conserved to different extents depending on the type of region they are found in. For example, one expects a sequence coding a binding domain of a protein to be highly conserved. Whether a mutation is silent or not further indicates the possibility of it "surviving" the process of evolution. These factors are important because, if sequences become saturated with polymorphisms, they become essentially random and no longer useful for this type of analysis. There are two main classifications: (1) it can be either "distance" or "discrete," or (2) it can be "exact" or "heuristic" (Table 13.1). Each combination can have a multitude of specific algorithms and implementations.

Discrete methods consider the differences in nucleotides directly, whereas distance methods first convert the data into a score for each pair of sequences based on the number of differences present. These dissimilarities can be partly shown by a parsimony tree (Figure 13.4(a)) and a distance tree (Figure 13.4(b)), which are identical except that the former shows additional information. A criticism of distance methods is that

TABLE 13.1 Four Main Branches of Tree Inference, as Combinations of Distance/Discrete and Exact/Heuristic Approaches

	Distance	Discrete
Exact	Minimum evolution	Maximum parsimony Maximum likelihood
Heuristic	UPGMA Neighbor joining	Bayesian inference

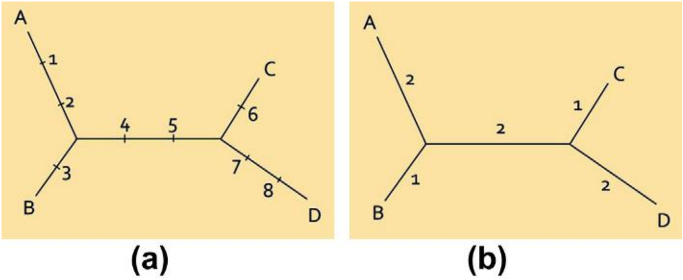

FIGURE 13.4 **Parsimony tree and distance tree.** (a) Parsimony tree. A–D represent sequences and numbers 1–8 represent variations in sequences. (b) Distance tree, identical to the parsimony tree but showing "distances" for each branch (i.e., the number of variations). *Acknowledgment: Hand-drawn by Emma Fitzgibbon based on example provided by the author.*

they are phenetic rather than cladistic. Another more subtle difference between the two, in how the data are treated, is whether to include or ignore insertions and deletions.

The other main classification of a tree-building method is whether it is exact or heuristic. Exact methods can be referred to as scoring or optimality, and some heuristics can be referred to as clustering. The aim of an exact method is to assemble all possible trees and score them based on a chosen optimality criterion. Clustering starts with a tree of three terminal nodes (only one unrooted tree of this size is possible); with each iteration of a process one additional node and branch are added until all sequences have been mapped to a final tree.

The advantage of clustering is its high interpretability, having only one tree as a result, but this is also its weakness as several trees may be almost as likely, based on the data, but will go completely unreported. In contrast, optimality/scoring presents all options with their associated scores to be ranked and appropriately interpreted. Clustering is appropriate for large amounts of data, particularly a large number of sequences rather than length of sequences. In these cases, generating and scoring all hypothetical trees is simply too computationally demanding. With five sequences, there are 15 possible trees; however, a meager increase to 10 sequences results in 2,027,025 possible trees (Table 13.2). These formulas, which describe how many trees are possible, are as follows:

1. Number of unrooted trees $=(2n-5)!!$, where "!!" denotes a double factorial. The double factorial of an odd number is the product of all positive odd integers up to and including the input itself; for example. $(2n-5)!!=(2*5-5)!!=5!!=1*3*5=3*5=15$, where $n=5$. Similarly, the double factorial of an even number is the product of all even integers up to and including the input. Including 1 in the case of an odd double factorial is, of course, mathematically equivalent to excluding it.
2. Number of rooted trees $=(2n-3)!!$

13.3.3 Methods of Tree Inference

There are a multitude of methods for tree inference, and it may be difficult to decide which is the best for, or the most appropriate, to the data, especially when there are an intermediate number of sequences. David Penny and colleagues suggest five criteria for assessing an algorithm or program [17]. Criterion 1 is that it is efficient (i.e., fast). As shown in the previous section, the increase in the number of possible

TABLE 13.2 Possible Tree Configurations

Sequences (n)	2n – 5	Unrooted Trees (2n – 5)!!
3	1	1
4	3	3
5	5	15
6	7	105
7	9	945
8	11	10,395
9	13	13,5135
10	15	2,027,025

Note: Given an increasing number of sequences, the increase in the number of configurations is given by $(2n-5)!!$.

trees with a given number of sequences is exponential, so speed is of great importance. If the number of sequences is too great, a global optimum cannot be found, a problem described as NP-complete [18]. NP-complete problems are grouped by the criterion that if one problem can be efficiently solved they all can, and that no efficient algorithm is known (and likely will never be known).

The second criterion is that the method is powerful—it does not require large numbers of data to come to a conclusion. With shorter sequence lengths, sampling errors are more probable, and as the length of a sequence is increased, the method may select different trees, converging on a single final tree at a particular sequence length. The smaller the length required for this convergence, the more powerful the method is.

The remaining criteria are consistency, robustness, and falsifiability. A model is consistent if, given ample data, it converges on the "correct" tree based on one's interpretation or model of molecular evolution. Robustness concerns whether the method is still accurate even when its assumptions are slightly violated. This can be tested by simulations on calculated datasets. Falsifiability is a general criterion for any scientific method, although many tree inference methods do not meet it. On a related note, one should be concerned about any method that does not indicate when its assumptions are violated (a clustering method will select one tree whether or not assumptions are violated). It may also be worth assessing scalability, that is, whether the method is accurate with both large and small datasets.

Maximum parsimony describes the adoption of the simplest interpretation of a set of data, which, in general, is often referred to as "Occam's razor" after the philosopher William of Ockham. Maximum parsimony is an exact method that uses discrete data. It selects the tree, of all possible trees, that requires the fewest evolutionary changes across all sequences being studied. It is not estimated where along a branch a change might have happened, only which change and on which branch. Maximum parsimony's benefits are that it is simple and easy to interpret and all trees may be scored and represented. It relies on the assumption that evolutionary change is rare and seeks to explain the variations present in the data by proposing the smallest number of mutational events.

Transitions are the replacement of a pyrimidine with a pyrimidine or a purine for a purine, whereas transversions are the replacement of a pyrimidine with a purine or vice versa. Transitions are substantially more common [19]. The simplest implementation of maximum parsimony is a model where transitions and transversions are equally likely and where the rate of evolution is consistent throughout the sequence length.

A more accurate model would assign a higher score (greater penalty) to transversions than to transitions. As mentioned earlier, different genomic regions are more prone to mutation and conservation of ancestral sequence, giving a varied rate of change throughout the genome. Another way that the method may be slightly altered to improve its approximation to actual events is to weight different sequence regions. In other words, different regions are scaled differently to represent the likelihood of a mutation in that particular region.

"Long branch attraction," first described by Joseph Felsenstein [20], is an example of a situation where maximum parsimony is prone to fail in selecting the correct tree, and the length of the branch represents the number of substitutions that occur along the branch. This is characterized by a small number of sequences that are either quite divergent or show highly varied rates of evolution; hence, some branches are much longer than others. In this situation, long branches tend to be grouped together because of an increased likelihood that the same substitutions are occurring along the branches. These corresponding homoplasies are being interpreted as homologies under maximum parsimony. They are much more likely to occur in smaller trees, where the lineages are relatively similar to begin with, than in distant branches of larger trees.

Where probability describes how often an event will occur out of a known set of all possible outcomes, likelihoods are relative to true probabilities and compare how likely are two or more events out of a set of events of unknown size. For example, a probability for rolling a 6 with a fair six-sided die is 1/6. Supposing the die has an unknown number of sides but we know 6 occurs twice as often as 5; then we cannot assign probabilities, but likelihood can still describe the *relative* probability of rolling a 5 compared to rolling a 6. Maximum likelihood [21] aims to associate a likelihood score to each tree—the likelihood that the input data have been produced by the tree. More formally it can be described by $\mathbf{L_D = Pr(D|}\mathrm{H})$, where the likelihood of the data occurring, $\mathrm{L_{D,}}$ is calculated by the probability of the data, D, given the hypothesis, H (the phylogenetic tree being assessed).

Maximum likelihood involves an explicit model that represents the probabilities of a position in the sequence changing from any base to any base (or the base remaining the same). Also required for maximum likelihood are, of course, the sequences and the proposed tree. Often the natural log of the likelihood, rather than the direct likelihood, is calculated. This is more prudent, seeing as the likelihoods are often small (the more data, the smaller they are). Using the model described, probabilities for the content of each nucleotide position can be generated (e.g., the likelihood that position 5 of the sequence is A, A, A, and G across four different sequences), given the model and the distances between the sequences on the hypothesized tree.

To generate the log-likelihood for a branch, the position-specific log-likelihoods are summed. The branch lengths are then optimized by projecting likelihoods for a variety of branch lengths and selecting the maximum. The maximum likelihood for the tree is then generated from these branch-specific likelihoods. One of the advantages of maximum likelihood is that the likelihood of the data occurring given a specific tree can be tested against the null hypothesis. Maximum likelihood allows a more detailed model than maximum parsimony, but it suffers even more with respect to computational time and large datasets.

Minimum evolution is similar to maximum parsimony but differs in that, rather than fitting and counting the individual nucleotide changes to a tree, it uses pairwise distances between sequences (a count of the number of nucleotide differences). The total length of the tree—that is, the sum of all branch lengths—is computed for each possible topology and the one with the smallest total length is selected. A disadvantage of this method is that, while it informs topology and evolutionary distance between sequences, it does not inform on specific base changes. Least squares methods are used to calculate the branch lengths based on the differences between sequences.

Clustering methods (which are heuristics) are much faster than exhaustive optimality criterion approaches, and so they are more appropriate for large datasets. Neighbor joining starts with a star tree. A pairwise distance matrix is calculated for the sequences and indicates the closest sequences to join with a new internal node. New internal nodes are iteratively added in this manner until the tree is fully resolved. Unweighted pair group method with arithmetic means (UPGMA) creates an ultrametric tree and relies on the assumption of a constant rate of evolution. Distance clustering methods such as these can be used to find a close approximation to the desired tree; exact methods can be used to optimize the tree based on a particular optimality criterion such as minimum evolution [22].

In summary, maximum parsimony, maximum likelihood, and minimum evolution are good choices when a small number of sequences are involved, or when one wishes to investigate a given set of phylogenies rather than infer them. Maximum likelihood allows us to more fully model evolution, so it is more powerful, although it requires knowledge of an appropriate model and more assumptions must be met. Minimum evolution is similar to maximum parsimony except that it assumes that the tree with the least evolutionary distance is the correct one. While these methods all perform very well with a trivial number of sequences, when a larger number of sequences is involved they become too computationally expensive. One must therefore use a heuristic approach.

By employing these methods, we are in effect estimating the true population using the sample that was sequenced. Bootstrapping involves resampling the sample population and reapplying the tree-finding method on each pseudoreplicate of the data. By doing this, counts for each tree can be generated and the ratio of a count for a tree to the total number of pseudoreplicate-generated trees can be generated as a score. These scores can be used as a measure of the method's precision, giving confidence that the selected tree is robust to sampling error, although it does not necessarily speak to the correctness of the prediction (e.g., because of an incorrect model or an unusual phylogeny). Felsenstein suggested that bootstrap values of >95 can be interpreted as being well supported. Bootstrap values are also often applied to each node of a tree.

A relatively new approach to tree building involves using Bayesian inference. Algorithms employing Bayesian inference are heuristics and can be applied with detailed models of evolution, as in maximum likelihood [23]. In contrast to the other methods outlined, bootstrapping is not required because the output expresses the uncertainty of each tree based on a probability distribution.

There are many programs that can be used for multiple-sequence alignment, tree inference, and preparing a diagram for presentation. A free tool that does all of these and uses a variety of tree inference methods (including all of those mentioned previously) is molecular genetics evolutionary analysis (MEGA). This tool is noncommercial, has a graphical user interface (GUI), and is available for Mac and Windows [24]. MrBayes is also worth mentioning as it can take advantage of modern graphics cards and their GPUs, which often now contain hundreds of cores [25], allowing for a highly parallelized version of a Bayesian inference algorithm that increases the speed of inference.

13.4 MOLECULAR GRAPHICS AND PROTEIN MODELING

Biological molecules such as proteins are complex structures, and representing their interpretable illustrations requires specialized techniques. Molecular graphics provides techniques to visualize and manipulate molecules on a computer. It can be used to give a general impression of a protein folding pattern; map residues that are assumed to be involved in a protein's function to a 3D representation of the protein to isolate an active site; classify and compare protein folding patterns; analyze changes between individual related structures or different conformational states of a single molecule; study the interaction of a ligand (small molecule) with a particular protein for drug development; and design and model a new structure. Because protein structure forms the main focus of molecular graphics, we discuss the basics of it in the following subsection.

13.4.1 Protein Stability

Proteins must fold to perform their intended biological function. They fold spontaneously to their active native 3D structure, which is determined by their corresponding sequence of amino acids. To form this native structure, a protein should optimize the interactions between its residues because each individual conformation of the main chain puts different residues in contact with each other.

The stabilities of different conformations are defined by the interactions of the side chains and main chain with each other and with the solvent environment of the cell. Moreover, the steric restriction on side-chain mobility is important for conformation stability.

13.4.1.1 Allowed Main-Chain Conformation

The main-chain conformation of each non-glycine amino acid is limited to two conformational states. This limitation comes from the angle of rotation around the peptide bond between two residues and the torsion angles between N–C_α and C_α–C single bonds of all residues. The torsion angle around the peptide bond is called ω while the torsion angles between N–C_α and C_α–C single bonds are called ϕ and ψ angles, respectively. Figure 13.5 shows the ϕ and ψ angles on a fragment of a polypeptide. The sequence of the ϕ, ψ, and ω angles define the conformation of the protein's main chain.

13.4.1.2 Permitted Torsion Angles

The peptide bond is planar and has two states: *trans*, $\omega \approx 180^\circ$, and *cis*, $\omega \approx 0^\circ$. In the *trans* configuration, the two alpha carbon atoms of the connected amino acids are on the opposite sides of the peptide bond, whereas in *cis* configuration they are on the same side of the peptide bond. In most cases, the peptide bonds in proteins are *trans*. This preference can be explained by the steric clashes that occur between groups attached to the alpha carbon atoms in *cis* form, which hinder formation of this configuration.

G.N. Ramachandran recognized that steric collisions between atoms prevent some combination of ϕ and ψ angles and, for the *trans* configuration, ranges of *ϕ* and *ψ* angles fall into defined regions in a graph called the Ramachandran plot (Figure 13.6) [26]. According to permitted ϕ, ψ, and ω angles, preferred conformations of the main chain lead to recurrent structures in proteins—namely, alpha helix, beta sheets, and turns.

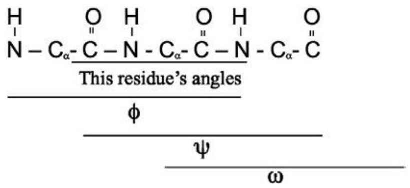

FIGURE 13.5 Conformation of each amino acid in a protein is restricted by rotation around two single bonds. Phi (Φ) is the torsion angle around the single bond between the nitrogen and the alpha carbon atom in an amino acid, while Psi (Ψ) is the rotation angle around the single bond between the alpha carbon atom and the carbonyl carbon atom. *Source: James Milner-White (2011), "Molecular Graphics," Lecture/Class, University of Glasgow, unpublished.*

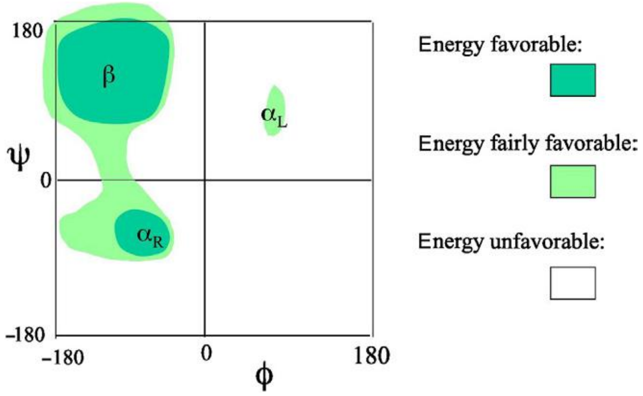

FIGURE 13.6 Ramachandran plot illustrating the allowed combination of Φ and Ψ torsion angles. The principle that two atoms cannot be in same place at the same time leads to exclusion of almost three-quarters of the plot. *Source: Adapted from Milner-White (2011). "Molecular Graphics," lecture, University of Glasgow.*

13.4.1.3 Alpha Helices

The alpha helix is a rod-like structure whose inner section is formed by a tightly coiled main chain, with its side chains extending outward in a helical array. The alpha helix structure takes advantage of the hydrogen bond between CO and NH groups of the main chain to stabilize. The CO group of each amino acid forms a hydrogen bond with the NH group of amino acid four residues earlier in the sequence. Therefore, in an alpha helix, all main-chain CO and NH groups are hydrogen bonded except in those amino acids close to the end of the helix.

The "screw sense" of an alpha helix can be right-handed (clockwise) or left-handed (counter-clockwise). Despite the fact that, based on the Ramachandran plot, both right-handed and left-handed alpha helices are among the permitted conformations, the right-handed alpha helix is energetically more favorable because of fewer steric clashes between the side chains and the main chain. Thus, all alpha helices in proteins are right-handed.

13.4.1.4 Beta Sheets

The beta pleated sheet—in short, the beta sheet—is another recurrent structure in proteins; it is noticeably different from the alpha helix. In a beta sheet, the main chain, called the beta strand, is fully extended rather than tightly coiled, and the side chains of adjacent amino acids point in opposite directions. A beta sheet consists of two or more beta strands linked by hydrogen bonds. Adjacent strands that form the beta sheet can either run in opposite directions (antiparallel beta sheet) or in the same direction (parallel beta sheet).

In antiparallel conformation, the CO and NH groups of each amino acid are hydrogen-bonded to the NH and

CO groups of the amino acid located in alignment on the adjacent strand. In parallel conformation, the NH group of each amino acid is hydrogen-bonded to the CO group of the amino acid on one side of the adjacent strand's inline amino, while the CO group is hydrogen-bonded to the NH group of the amino acid located on the other side of the adjacent strand's inline amino acid. Typically, beta sheets consist of 4 or 5 beta strands where they can be all antiparallel, parallel, or mixed. Beta sheets can be relatively flat or to some extent twisted, which makes them more structurally diverse than alpha helices.

13.4.1.5 Turns and Loops

Proteins typically have compact, globular shapes formed by combination of alpha helices and beta sheets. However, to obtain these compact shapes, they require reversals in the direction of their chain. The reverse turn, also known as the beta turn or hairpin bend, provides a common structure to satisfy the chain reversal requirement. To stabilize this structure against sudden changes in direction, the reverse turn forms a hydrogen bond between the CO group of the "i" residue and the NH group of the "i+3" residue of a polypeptide chain.

Loops are another type of structure responsible for chain reversals and are more intricate than reverse turns. Although they do not have periodic structures similar to alpha helices and beta sheets, they are rigid and well defined most of the time. Reverse turns and loops always lie on the protein's surface and hence often participate in the interaction of the protein and other molecules.

The three-dimensional structures of proteins, which consist of different combinations of the recurrent structures, are stored in the Protein Data Bank (PDB) repository as text files in the .pdb file format.

13.4.2 Protein Data Bank File Format

The pdb file format provides the atomic coordinates for the main-chain and side-chain atoms, secondary structure assignments, and atomic connectivity. Pdb files may provide only the asymmetric unit—the smallest portion of a molecule that, upon symmetric operations such as rotation and translation, can be used to assemble the whole molecule. Asymmetric units are usually used by crystallographers to refine the coordinates of the structure against the experimental data.

A typical pdb file has a 4-digit code of the form "1xyz" and contains the following sections: title, primary structure, heterogen, secondary structure, connectivity annotation, miscellaneous features, coordinate, and connectivity [27].

Title. This section describes the experiment and the biological macromolecules present in the file.

Primary structure. This section contains the sequence of residues in each chain of the protein. Furthermore, it accommodates the chain identifiers and sequence numbers used by other records to link to this section.

Heterogen. Any nonstandard residues such as ions, prosthetic groups, and solvent molecules are described in this section. Each nonstandard residue is assigned the sequence number, chain identifier, and number of that type of residue described in the coordinate section.

Secondary structure. This section describes the helices and sheets that are distributed along a protein chain. Helices are named, numbered, and classified by type. Moreover, the total length and the start and end residues of the helix structure are noted. Sheets are described using the same factors.

Connectivity annotation. This section specifies the existence and location of linkages between residues which are not directly expressed by the protein's sequence of amino acid of the protein.

Miscellaneous features. Properties such as environments surrounding a nonstandard residue or the assembly of the active site may be provided in this section.

Coordinate. This section consists of atomic coordinates for both standard residues and nonstandard chemicals such as water molecules or atoms presented in Heterogen section.

Connectivity. Information regarding the atomic connectivity between atoms, for which coordinates are provided in coordinate section, can be retrieved from this section.

Molecular visualization systems such as PyMOL [28] or Jmol [29] can be employed to view the three-dimensional structure of proteins described in pdb files. The Java applet version of Jmol is particularly useful as it may be embedded into web pages; however, PyMOL is more extensive in terms of features. Both are open-source visualization tools that show structures using various standard representation styles (Figure 13.7) and output them as either images or video files.

Two standard representations are ball-and-stick and space-fill. Ball-and-stick represents atoms by appropriately colored balls and the bonds between them as lines or "sticks." This is useful for visualizing the geometry of the bonds between atoms, but it gives no indication of the space occupied by the atoms. Space-fill, on the other hand, shows the space occupied by the atoms (since each atom is represented by a sphere with the radius equal to its van der Waals radius), which allows the user to more easily identify steric clashes.

Another useful representation is one in which beta sheets and alpha helices are clearly shown by cartoons and ribbons. The cartoon model simplifies protein structure to illustrate the direction of the protein chain, protein folding, the element of the secondary structures, turns and loops,

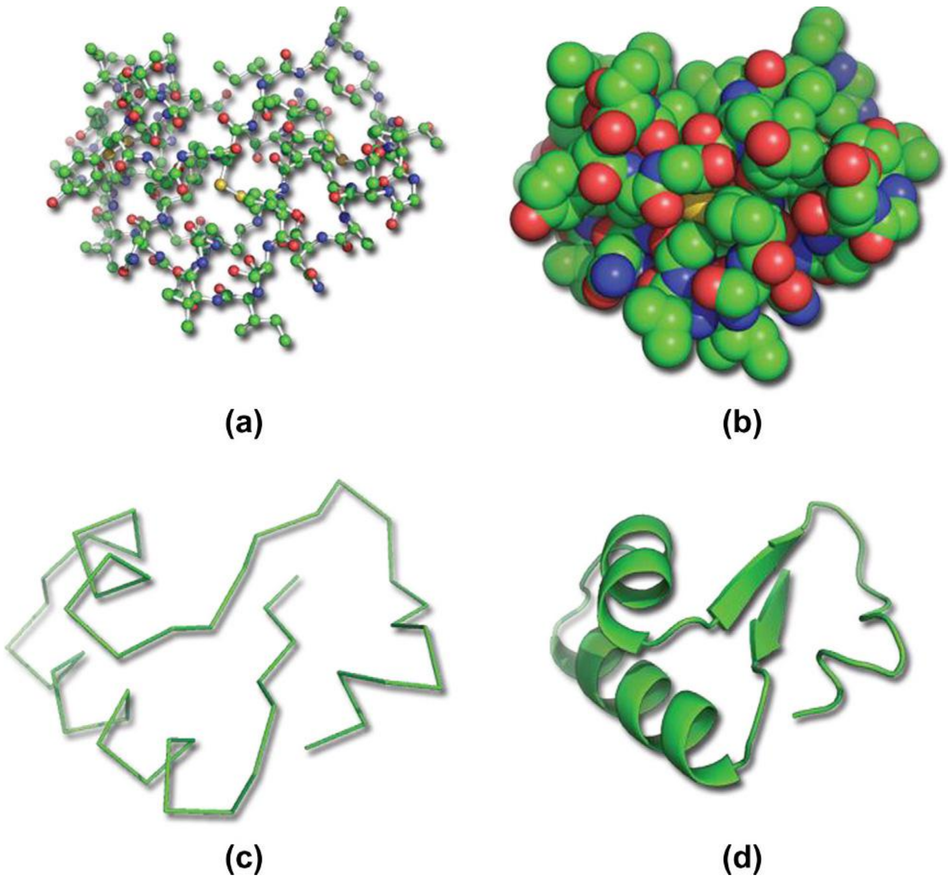

FIGURE 13.7 **Various representation methods as depicted by PyMOL.** The images show (a) ball-and-stick, (b) spacefill, (c) ribbon, and (d) cartoon.

and domain structures. The ribbon model can be categorized as a cartoon model, but the algorithm used to generate ribbon representation is different. The ribbon model employs the B-spline curve to render proteins, whereas the cartoon model is derived from models of protein secondary structures hand-drawn by Richardson [30].

13.4.3 Protein Modeling

Despite the increasing success of approaches for obtaining protein sequences, for the vast majority of known sequences, no structural information is available. The goal in protein modeling is to predict the protein's structure from its sequence with a level of accuracy comparable to the result acquired experimentally. This can fill the gap in structural knowledge in fields such as structure-based drug design, which otherwise must rely only on experimentally derived structures. Moreover, protein modeling is the only way to acquire some knowledge of protein structure, when experimental methods fail. For instance, many proteins are too large for NMR analysis or cannot be easily crystalized for X-ray diffraction methods. Methods for predicting the 3D structure of proteins include homology modeling, fold recognition, and de novo structure prediction.

13.4.4 Homology Modeling

Among approaches to predicting 3D structures, homology modeling can be considered as the easiest because of two observations. First, the structure is determined by the 1D sequence of the protein's amino acids [31]. Thus, the amino acid sequence should contain enough information to obtain the structure. Second, as proteins evolve their structure and sequence change. However, the rate of modification is much slower in structures than in sequences [32,33]. This observation is summarized in Figure 13.8.

Based on the figure, if the percentage sequence identity of two sequences is above the threshold, it is likely that they fold into approximately the same structure. If, on the other hand, the percentage sequence identity falls below the threshold, it is not evident whether two sequences fold into similar or different structures.

The sequence with a known structure is called the template, while the sequence with an unknown structure is called the model. Simple similarity search tools such as

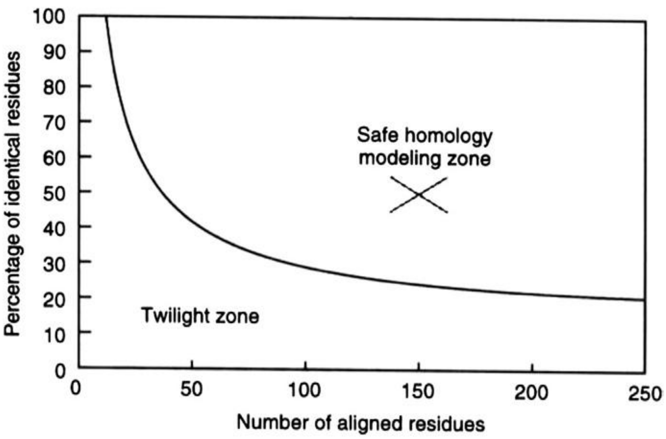

FIGURE 13.8 **Relationship between percentage sequence identity and number of aligned residues.** The zone above the threshold is called the "safe zone"; the zone below is called the "twilight zone." For longer sequences, the percentage identity that falls in the safe zone can be less than 25%. *Source: Adapted from Sander et al.* [31].

BLAST (local alignment) [7] and FASTA (global alignment) [34] can determine the identity between the template and the model. Once the percentage identity in the aligned region of the template sequence and the model sequence falls into the safe zone shown in Figure 13.8, a model can be built.

Homology modeling (Figure 13.9) is a multistep procedure, including the following steps: template recognition and initial template–model sequence alignment; alignment correction; backbone generation; loop modeling; side-chain modeling; model optimization; and, finally, model validation.

13.4.4.1 Template Recognition and Initial Alignment

In the safe homology modeling zone, the percentage identity of the model and the template sequence is high enough to be detected with BLAST or FASTA. To identify the template sequence, either program compares the query sequence with all sequences of known structure in the Protein Data Bank repository. It is possible to use the sequence with the highest sequence identity as the template sequence or to combine multiple sequences into one template sequence. The latter method is used by the Swiss-Model [35] and Robetta servers [36].

13.4.4.2 Alignment Correction

After retrieving the template sequence, more sophisticated methods can improve the performance of the final model. For instance, in regions where the percentage sequence identity is very low, it might be difficult to align the template and model sequences. One solution is to increase the identity percentage via other sequences from other homologous proteins, which are found by a multiple-sequence alignment, and use implicit structural information from the alignment. For example, if at certain positions of the sequences only hydrophobic residues are found, it is likely that these residues are located at the hydrophobic core and are therefore "buried." Position-specific scoring matrices, also called profiles [37,38], consider these features during the alignment procedure; programs, such as MUSCLE [39] and T-Coffee [7], use these profiles to improve multiple-sequence alignment.

13.4.4.3 Backbone Generation

Once the alignment is ready, the model-building process starts off with backbone generation. In the case of a single template, this is trivial, and one can simply transfer the backbone coordinates of aligned residues and the side-chain coordinates of conserved residues. In the case of multiple templates, an average structure is used where individual template contributions are weighted by the local degree of sequence identity.

13.4.4.4 Loop Modeling

As described in Section 13.2.4, sequence alignments may contain gaps; the same also occurs with model and template alignment. These gaps can be easily addressed by omitting the residues from the template sequence. Similarly, inserting residues into the model sequence addresses the gaps in the template sequence. Both cases therefore lead to conformational changes in the backbone. On the other hand, these changes rarely occur in regular secondary structures such as alpha helices and beta sheets. Thus, it is more appropriate to "shift" all insertions and deletions to turn and loop structures, which can solve the problem of insertions and deletions; however, changes in loop conformation are difficult

to predict. There are two main approaches to modeling loops: knowledge based and energy based.

Knowledge-based loop modeling searches the Protein Data Bank repository for loops of the same length and similar end-point geometry. Later the coordinates of the identified loop are transferred. Energy-based loop modeling utilizes an energy function to determine the quality of the loop and find the best loop conformation; it then performs a mineralization of the structure using either Monte Carlo [40] or molecular dynamics [41] techniques.

13.4.4.5 Side-Chain Modeling

In homologous proteins, where the percentage sequence identity is over 40%, the side-chain conformations (rotamers) of conserved residues exhibit the same orientation [42]. Therefore, it is possible to directly transfer the conserved residues from the template sequence to the model sequence, as mentioned earlier. However, this is only applicable with high levels of sequence identity. To overcome this problem, side-chain modeling uses a knowledge-based approach, where libraries of common side-chain conformations are employed to position side chains. Each conformation in the library is scored with a variety of energy functions and the best one is used. For this reason, in cases of low levels of similarity rotamer prediction can be computationally expensive.

13.4.4.6 *Model Optimization*

To predict side-chain conformation with high accuracy, one needs the correct main-chain conformations, which in turn depend on side-chain conformation. Thus, there is a loop in modeling main-chain and side-chain conformations, a problem solved by iteratively modeling the structure of the main chain and the side chain until the solution converges: First, the structure of the rotamers are predicted; following that, the structure of the main chain is remodeled to accommodate rotamers; finally, the rotamers are refitted to a new main-chain structure in a process that consists of a series of rotamer predictions and energy minimization steps. Another approach to optimizing the model is simply running a molecular dynamic simulation of it. This simulation follows the motions of the protein and mimics the folding process itself.

13.4.4.7 *Model Validation*

Errors in homology modeling depend on two factors: the percentage of sequence identity between the template and model sequences and the number of errors in the template sequence. If the identity between template and model sequences is higher than 90%, the accuracy of the predicted model is comparable to experimentally determined structures [32]. An identity percentage of 50–90% leads to a model with considerable local error, while an identity percentage of 25–50% often leads to large error regions, in which case homology modeling is not applicable.

Errors in the protein structure can be estimated either by computing the model's energy or by determining the normality indices. The former checks the bond length and the bond angles and determines if they are within the normal range, while the latter compares the characteristics of the predicted structure with those of the real structure. These characteristics include distribution of polar and nonpolar residues, direction of atomic contacts, and so forth.

13.4.5 Fold Recognition

Homology modeling is useful when the model protein (with a known sequence and an unknown structure) is related to at least one other protein with both a known sequence and a known structure. The quality of the predicted structure by homology modeling depends on the degree of similarity between the model and template sequences. If the similarity is very low, homology modeling of the query protein does not yield a meaningful result. Fold recognition can be employed in this situation. Its goal is to answer this question: Given a library of known structures and a model sequence, does the query protein share a fold with any of the known structures in it? One of the fold recognition methods is called threading and is discussed in the next section.

13.4.6 Threading

The idea behind threading is simple: based on each known structure in the library, build a rough model of the query protein and explore different possible sequence alignments for it and for the known-structure protein. Threading thus systematically explores many different alignments to find the best model. Both threading and homology modeling utilize sequence alignment of the query protein and the known-structure protein to predict the former's 3D structure. Table 13.3 compares homology modeling and threading.

Since threading builds one model per each known structure in the library, selecting the best requires scoring. Moreover, a way to evaluate the scores is required; otherwise, it is not clear whether a scoring model is correct.

One effective scoring approach is derived from patterns of residue neighbors in the library of known structures. First, the distribution of inter-residue distances for all 20 × 20 residues is retrieved from the known structures. Next, for each pair of residues, a probability distribution is derived based on the separation of the pair in physical space and in the amino acid sequence. Once the probability distribution for each pair is computed, one can estimate the performance of different models based on the level of agreement between them and known-structure distributions. The Boltzmann equation, which relates probabilities and energies, can be employed to derive an energy function from the probability distribution. This energy function can be used to evaluate the score of the threading model.

TABLE 13.3 Comparison of Homology Modeling and Threading

Homology Modeling	Threading
Identify homologous proteins	If no homologous proteins exist; try all present folds in library
Determine best alignment	Explore various possible alignments
Optimize only one model	Find best model among many rough models

Note: Homology modeling deals with one set of alignments; threading, many possible alignments. The goal of homology modeling is a very detailed model; threading produces a rough model.

13.4.7 *De Novo* Structure Prediction

The goal of *de novo* structure prediction is to predict the 3D structure of the query protein only from its amino acid sequence. In contrast to homology modeling and fold recognition, *de novo* prediction does not rely on homology between query sequence and known-structure sequence. Thus, it considers a noticeably larger conformational landscape than homology modeling and fold recognition, since both of latter only explore regions of space near an initial template structure. Sampling this large landscape is computationally expensive, to the extent that it can be considered a limitation of de novo methods. Global search algorithms, such as Monte Carlo Metropolis, can be employed to ensure that important regions of the conformational landscape are sampled. *De novo* methods are also known as *ab initio* methods.

De novo methods have been shown to be successful for predicting secondary structures and local structure patterns [43,44], although, despite recent progress, there are many problems that need to be addressed before a consistent and reliable prediction can be obtained.

13.5 BIOINFORMATICS DATABASES

In the post-genome era, there is not only a wide range of database content but also a vast amount of choice within each discipline or data type—from extremely large and broadly themed international repositories to databases solely devoted to, for example, the targets of an individual transcription factor [45]. It is advantageous for researchers in most disciplines in medicine and research biology to exploit at least some of these valuable resources.

The aim of this section is to (1) identify key fields where large databases are influential in the biosciences; (2) very briefly explain why they are useful and describe their scope; and (3) outline some of the most prominent and useful databases. The two most valuable resources are the National Center for Biotechnology Information (NCBI) which is part of the National Institutes of Health (NIH), and the European Molecular Biology Laboratory's European Bioinformatics Institute (EMBL-EBI). Much of the information given here is provided by these organizations, and both provide the option of a general search of many of their databases through one interface (Entrez, Ensembl). File types are varied throughout IT and bioinformatics, and some are individual to just one database. The most common will be outlined, with the exception of pdbs, which were described in Section 13.4.2.

13.5.1 General Sequence Databases

Compared to older technologies, modern massively parallel sequencing technologies are capable of generating a vast amount of information at a fraction of the cost, and they have revolutionized genetic research. This explosive growth in fact exceeds the growth of storage capacity and has resulted in new challenges for data storage, retrieval, and analysis [46]. The primary resource for raw sequence data, both DNA and RNA, is the Sequence Read Archive (SRA), a public repository of data from next-generation sequencing (NGS) machines.

The SRA is part of the International Nucleotide Sequence Database Collaboration (INSDC), which is a collaboration of three partners: EBI, NCBI, and the DNA Data Bank of Japan (DDBJ) [47]. Each partner uses its own graphical user interfaces to provide electronic access to the database stored on their servers. A programmatic way to access the information is through the R/Bioconductor package, SRAdb [48], which allows the user to search through an SQL database of SRA metadata, download the appropriate data, and interactively view it through the Integrated Genomics Viewer (IGV). The metadata include information about the study, sample, experiment, run, analysis, and submission. EBI and NCBI also offer programmatic methods of accessing their database (using the ENA browser REST URLs and the SRA System Development Kit, respectively); however, Bioconductor contains many useful analysis packages and so it may be more convenient to use SRAdb.

The SRA accepts base calls, quality scores, and sequence alignments through any of its three partners and, in 2011, had accumulated over 100 terabases of "reads" (a term often used in concordance with NGS technologies to denote a short contiguously sequenced length of bases). Because of the number of currently available technologies, the number of upcoming technologies, and the variety of associated file formats, compatibility is an issue. The solution is that data in some (newer) file formats are provisionally available only as they are, whereas data submitted in already widely used formats is validated and made available in standard formats. Regardless of which of the three SRA partners a dataset is uploaded to, it is shared among all. As a result, each database is almost identical, although methods of access and databases linked to the SRA data vary.

The largest individual project in the SRA is 1000 Genomes, which is an international effort and contributes almost a third of the bases in SRA [49]. The aim of the project is to investigate human genetic variation across geography and phenotype, and in so doing promote understanding of the genetic contribution to human disease. The 1000 Genomes Project Consortium describes the genomes of 1092 individuals from 14 populations throughout the world. The pilot phase—in which >95% of common variation (>5% frequency) was discovered—showed that a combination of methods could ensure a balance between cost-effectiveness and power to describe all but the rarest of single-nucleotide polymorphism (SNP) and indel (insertion/deletion) variants. The methods employed were low-coverage whole-genome sequencing, deep exome sequencing, and extensive SNP genotyping. The consortium reported 1.4 million short indels, more than 14,000 large deletions and 38 million SNPs, and covered up to 98% of accessible SNPs at a frequency of 1% in related populations.

It can be said then that 1000 Genomes provides extensive coverage of common variants and high coverage of low-frequency variants, but poor coverage of the rarest variants. As well as providing a resource for molecular research in general, the consortium has uncovered interesting summary information about the genome—for example, that each individual "carries" hundreds of rare noncoding variants at conserved sites which potentially alter transcription factor binding or have other expression-related effects. While 1000 Genomes data is part of the SRA, it also has a stand-alone website (www.1000genomes.org). In addition, it submits its findings to genetic variation databases such as NCBI's dbSNP (www.ncbi.nlm.nih.gov/SNP).

EBI makes SRA accessible through the European Nucleotide Archive (ENA) [50]. In 2013, ENA published updates to the effect that the SRA had tripled in size since 2011 and was consistently doubling in size every ten months; it now comprised data from over 14,000 studies. Furthermore, comparable growth is expected for another five to ten years, even under modest predictions [51]. In addition to the SRA, ENA also has the Trace Archive and the EMBL-Bank. The Trace Archive is similar to SRA: it is a large repository of raw nucleotide sequences maintained by each INSDC partner; however, it is used primarily for older lower-throughput gel/capillary sequencing, which typically results in longer reads but lower overall throughput than those obtained by NGS technologies. EMBL-Bank is the continuation of the EMBL Nucleotide Sequence database, containing nucleotide sequences and their associated biological annotations and bibliographic information. Unlike the SRA or Trace Archive data, nucleotide sequences housed in EBML-Bank are processed rather than raw—although many of the data are based on the raw data in the SRA and the Trace Archive.

NCBI's GenBank is similar to EMBL-Bank as a repository for nucleotide sequences and their corresponding biological and bibliographic annotations. Although these two resources are not strictly part of the INSDC, they do share data with each other and with DDBJ on a daily basis [52]. GenBank itself subdivides into three smaller databases: Expressed Sequence Tags (EST), Genome Survey Sequences (GSS), and the Nucleotide database, which holds all the remaining data, including whole-genome shotgun data, representing most of the data in GenBank.

When using any of the aforementioned databases, it should be remembered that entries are submitted by thousands of researchers internationally and are not extensively reviewed. There is, therefore, both an extremely high level of redundancy and a varying level of quality and correctness of the associated annotations. Another useful sequence database maintained by NCBI is RefSeq [53], a nonredundant database that is highly curated and, while not part of the INSDC, derives nonredundant sequences from INSDC data. Similarly UniGene, rather than describing genes, as the name implies, nonredundantly describes all known transcripts that originate from a particular locus.

All of these resources are described as open access; that is, access is free and unrestricted. In some experiments, where consent documents have not included open access, data sharing must be restricted. For example, a restriction may be that the data are only to be used for specific research or provided only to bona fide researchers. In these cases, patient confidentiality must of course be maintained with appropriate security measures. To avoid mistakes, access should be granted only by the access-granting organization (DAO) and not by the database administrators. EBI's European Genome-Phenome Archive (EGA) and NCBI's database of GenoTypes and Phenotypes (dbGaP) are examples of such databases; they store data on entire experiments, including sensitive but well-characterized patient phenotype information corresponding to the experimental data [54].

Datasets from these resources can potentially be used for a range of applications, from testing new or developing software on appropriate real data to conducting meta-analysis over several datasets of the same type. There are pitfalls, however. One problem is that limited public reporting of secondary research on these datasets to some extent obscure the true extent of its impact. Another is that no consensus exists as to whether additional consent is required to submit the datasets to such a database, even with security restrictions. In a survey about this issue, participants stated that it was very (69%) or somewhat (21%) important that they be asked permission, indicating ethical consent should be a concern [55].

13.5.2 Gene Expression

One of the many technologies heavily influenced by the advances of the Human Genome Project is the microarray. Microarrays are flat surfaces or "chips" on which a 2D array of probes is located, all of which are used to assay the same sample. In some cases, there are several sets of probes per microarray and many samples may be assayed. Each "spot" on the array tests for the presence of a specific biomolecule of a particular type, usually DNA. The probes, which fluoresce when binding their target molecule, are hybridized either to the surface (as in Affymetrix technology) or to microscopic beads located in wells on the surface to help resolve problems arising from spatial technical effects (as in Illumina technology). These devices are perhaps best known for assaying gene expression, although they have many other uses, including the investigation of protein binding and DNA methylation. In practical terms, a gene expression microarray allows the researcher to see which genes have an altered expression—for example, depending on different phenotypes or drug doses.

NCBI's GEO [56] and EBI's ArrayExpress [57] are the main databases for array-based data, including various types of microarray and some sequence-based data such as RNA-seq. RNA-seq is essentially a method for estimating gene expression levels by sequencing cDNAs and aligning them. It is generally seen as a more powerful tool, and it has been suggested that it will replace gene expression microarrays as the cost of sequencing decreases [58]. Microarrays are still a valuable technology, being cheaper, less complicated, less data-heavy, and simpler to analyze. RNA-seq, however, can detect SNPs and other genetic variations, fusion genes, and levels of different splice variants. It has also been suggested that the two technologies should be used together where possible to detect the maximum coverage of the transcriptome [59]. All data in GEO and ArrayExpress must adhere to "minimum information about a microarray experiments" (MIAME) [60] or "minimum information about sequencing experiments" (MINSEQE) [61]; these are standards dictating that enough information must be included for a second party to sufficiently analyze and/or recreate the experiment. In 2012, ArrayExpress reported having over 30,000 datasets—27,000 more than it had in the previous two years. Both GEO and ArrayExpress continue to grow quickly, and both tools, along with ways to link them to popular tools, are in development [62].

In some cases, rather than interrogating a specific case-control experiment dataset, one might simply wish to know which tissues normally express a gene and to what extent. BioGPS allows searching by several types of identifiers, including gene symbol, gene ontology, Affymetrix ID, and genomic interval [63]. The result is a bar chart of expression values for a list of tissues that have been assayed by Affymetrix microarrays. Reports of various annotations and a gene summary are also shown alongside the data. To identify genes that are normally similarly expressed and so potentially share similar roles or regulatory pressures, their expression profile may be searched against other expression profiles for one with a correlation surpassing a preselected cut-off. Another, more comprehensive take on the theme, is EBI's Gene Expression Atlas [64]. This web service offers similar searches and output, but across a variety of biological conditions and diseases as well as across tissue and cell types. Graphical displays are employed, and the user can obtain a view of many types of biological contrast from a single report page; the user can also see, for each tissue, the number of studies in which the gene showed up- and down-regulation, and obtain links to the data in ArrayExpress as well as in publications describing the experiments.

13.5.3 Noncoding Sequences and Epigenomics

The term "junk DNA" dates back to 1972 and describes the large proportion of noncoding DNA in the human genome which at the time had no known function [65]. Since then, many types of regulatory noncoding genetic sequences have been recognized. Some of this "junk DNA" is in the form of repetitive elements that may span one-half to two-thirds of the genome [66]. Repetitive DNA has been shown to perform a variety of functions, one of which is serving as a boundary for heterochromatin domains [67]. It has also been shown to influence various diseases—for example, Huntington's disease, which is caused by a trinucleotide repeat in the gene HTT [68]. Repbase Update is the most commonly used database for repetitive DNA elements; it reports on a diverse range of repeat families and subfamilies [69] and contains over 3600 annotated repeat sequences, some unique to it. Repbase Update may be used either to identify genomic locations of repeats or to screen them from a sequence so that only the nonrepetitive regions are left uncensored (repeat bases are converted to the letter "N").

Promoters are genetic sequences that are usually located upstream of their corresponding genes; they are usually a few hundred base pairs in length and are involved in the initiation of transcription, where they act as a binding site for the transcription initiation complex. Some genes have multiple promoters, and different promoters for the same gene may be activated under different circumstances, causing differential expression [70]. The Eukaryotic Promoter Database (EPD) contains experimentally defined promoters of RNA polymerase II (the enzyme responsible for mRNA synthesis) [71]. These data have been collected over 25 years, beginning with experiments mapping transcription start sites (TSS) for individual genes and later the use of carefully selected NGS datasets. The focus of EPD was originally on high quality, whereas a new section, called EPDnew, focuses more on quantity, with the aim of identifying promoters for all genes over several model organisms [72]. Another recent addition is the use of chromatin signatures and mRNA 5′ tags to help identify genes with lower expression.

Transcription factors (TFs) are proteins that bind to DNA, thereby influencing gene expression. Those that promote the recruitment of RNA polymerase up-regulate a gene and are said to act as activators; those that block recruitment and down-regulate are said to be repressors. Possibly the most popular database for TFs is Transfac; however, only an older database version with an interface of reduced functionality is available to the public [73]. Transfac provides data for experimentally proven TFs and their corresponding genes, and provides predictions for potential TF-binding sites. One recently published alternative database is AnimalTFDB, which allows browsing by TF family and species as well as the use of free search terms [74].

MicroRNAs (miRNAs) are short noncoding RNA molecules (~22 nucleotides in length) that function in both transcriptional and post-transcriptional eukaryote regulation [75]. They are known to "silence" or "knock down" genes either by degrading mRNA or by preventing transcription or translation via binding to the corresponding DNA or mRNA, respectively [76]. MirBase is probably the most useful place to initially look for miRNA annotations, sequences, and so forth. Each entry has a thorough report page including sequence, genomic coordinates, and links to scientific papers on PubMed. Unfortunately, MirBase does not provide information on target genes [77], but many websites provide this functionality, describing experimentally validated targets, targets predicted by various algorithms, or both. A recent web application, miRWalk, summarizes the information from eight of these databases [78].

There are many definitions for epigenetics, a recent one being "stably heritable phenotype resulting from changes in a chromosome without alterations in the DNA sequence" [79]. Epigenomics is the study of the complete set of at least one of these changes and, functionally speaking, epigenetics experiments often use chip-based or sequencing-based technologies to investigate DNA methylation or histone modification. The Epigenomics database at NCBI stores data for over 4000 experiments focusing on various species, biological samples, and "feature types" (i.e., epigenetic modifications) [80]. It is essentially a subset of GEO, but with a modified interface specifically for those searching for epigenomics data.

13.5.4 Proteins, Metabolites, and Pathways

The Universal Protein Resource (UniProt) is a comprehensive database of structure and annotation and is divided into four main components: UniProt Knowledgebase (UniProtKB), UniProt Reference Clusters (UniRef), UniProt Archive (UniParc), and UniProt Metagenomic and Environmental Sequences (UniMES) [81]. UniProtKB is divided into a TrEMBL section, which stores automatically annotated and unreviewed sequences, and a Swiss-Prot section, which stores manually annotated and reviewed sequences. UniProtKB/TrEMBL contains ~40,000,000 sequences comprising ~13,000,000,000 amino acids; UniProtKB/Swiss-Prot contains ~540,000 sequences comprising ~190,000,000 amino acids.

UniProtKB/Swiss-Prot is less redundant in that it stores only one entry and ID corresponding to each gene. UniProtKB/TrEMBL may store several entries per gene depending on nonsynonymous genetic variation, alternative splicing, and fragmentation (these entries are simply the translations of sequences found in EMBL-Bank/GenBank/DDBJ). For this reason, Swiss-Prot has become a valuable tool for proteomics, where very minor variations are not highly important; often more important is that corresponding proteins be given common names to simplify analysis and literature/database searches and that protein levels be compared (e.g., between case and control groups). Data from over 28,000 proteomics experiments can be found and downloaded from the Proteomics Identification Database (PRIDE), and UniProt can be used to convert redundant IDs into SwissProt IDs [82]. The TrEMBL section, on the other hand, may be more useful for investigating differences in structure and function due to nonsynonymous genetic variation/mutation/alternative splicing. Each report page offers a wealth of information on the protein of interest, including post-translational modifications and links to other resources, such as the Protein Data Bank [83].

UniParc is an archive of protein sequences extracted from public databases; however, no report pages are given and all associated data must be retrieved through links to the various sources. UniRef stores clustered sets of sequences from UniProtKB and UniParc in such a way that searches result in clusters of related proteins (e.g., isoforms and proteins from orthologs). Unlike UniParc or UniProtKB/TrEMBL, UniRef merges sequence fragments to reduce redundancy and simplify interpretation; however, isoforms are kept as separate records to include more "resolution" than is available in UniProtKB/SwissProt. In a sense, one can say that none of the UniProt databases are redundant and that each uses its own definition of redundancy—redundant by gene, redundant by splice variant, and so forth. The UniMes database contains clusters of sequences from metagenomics clusters obtained from experiments such as Craig Venter's Global Ocean Sampling Expedition; the sequences cannot be found anywhere in UniProt except in UniParc.

The Human Metabolome Database describes small molecule metabolites in humans, containing and linking three types of data: chemical, clinical, and molecular biology/biochemistry [84]. It holds more than 40,000 metabolites, both water-soluble and lipid-soluble. Some of them are called "detected" because they have been experimentally confirmed, while others are called "expected" because of their biochemical pathways or high human exposure. It is possible to browse by biofluid or pathway, or to search via a range of methods, from peak matching to chemical formula. The standard report page for a particular metabolite gives its description, chemical taxonomy, biological and physical properties, and links to various useful sites such as Kyoto Encyclopedia of Genes and Genomes (KEGG) and NCBI's PubChem (pubchem.ncbi.nlm.nih.gov/).

Various interaction and pathway databases can be important for downstream analysis of a wide range of experiments. Some are simply for storage and searching whereas others provide extra functionality. KEGG Pathway is a large well-curated database with impressive zoomable "global" maps that show large sections of metabolism in one view. However, part of its service is now commercial [85]. A similar database with fewer compounds but more pathways and reactions, and slightly more extensive pathway report pages, is MetaCyc [86]. Pathway Commons collects data from a range of free-access databases and provides a link for interactive pathway viewing by Cytoscape [87]. Reactome allows mapping of a list of IDs to its database of pathways, allowing the user to see if a set of biomolecules of interest are heavily involved in one pathway in particular [88]. PathVisio is a tool for viewing and editing the pathways in WikiPathways [89,90], which is a noncommercial site unrelated to Wikipedia but is also an open and collaborative platform. Because PathVisio is written in Java, it is cross-platform; also, its website provides user tutorials.

The pathways just discussed are only a few of the choices available, and only some of their "front-end" functionality was described. To give the reader an idea of the scope of available resources, it is worth mentioning Pathguide (http://pathguide.org), which describes itself as a "pathway research list." A search of their website with no terms selected to narrow it (e.g., by organism) yields "556 biological pathway related resources and molecular interaction related resources."

13.5.5 Pharmacogenomics

As NGS costs drop and more genetic variation becomes annotated, personalized medicine becomes more realizable. With this in mind, Pharmacogenomics Knowledge Base (PharmGKB) has been set up to collect information about genetic variation and its influence on drug response, and to make this information freely available [91]. PharmGKB makes use of a range of data, from genetic to clinical, and the user can browse it by gene, drug, disease, or pathway; each gene, drug, or disease record is marked to indicate how fully annotated it is—for example, whether there is clinical data or whether genetic variants are annotated as being associated with a particular drug. Over 100 pathways are curated by PharmGKB (in addition to links) and have thorough descriptions that include external links to evidence and various options for downloads and internal links for pathway components. There is also a search bar with a Google-like auto-complete function for finding drugs, genes, and so forth. PharmGKB and the NIH Pharmacogenomics Research Network (PGRN) are making a collaborative effort to develop genetics-based drug dosing guidelines. PharmGKB recently added these data to the database and correspondingly updated its web interface.

13.5.6 Annotation

One of the most useful annotations in biology is gene ontology (GO) [92]. GO terms represent a standardized classification of genes and their products and are split into three broad types: biological process, cellular component, and molecular function. Each term is part of a hierarchy—for example, "mRNA splicing, via spliceosome" is a child term of "mRNA processing." Gene ontologies are useful for term enrichment analysis where an algorithm detects if any terms are over-represented in a list of genes of interest, such as differentially expressed genes. The more similar a model, the more useful, which is why gene ontologies are not static but changing, with each version subject to the Gene Ontology Consortium's review and benefiting from the scientific community's advice. When a term is associated with a gene, an evidence code (e.g., "IMP: inferred by mutant phenotype" or "ISS: inferred from sequence or structural similarity") is also recorded so that the reader or algorithm may filter out associations with weaker evidence.

Online Mendelian Inheritance in Man (OMIM) is an extensive database of diseases with genetic components [93]. Its entries have MIM numbers—unique 6-digit identifiers wherein the first digit describes the method of inheritance (e.g., X-linked, autosomal). A character before the code describes additional details, and a number after a decimal point at the end of the code denotes an allelic variant.

The NCBI Taxonomy Database is for INSDC members and was developed in consultation with those members and external advisors [94]. Almost 280,000 species have been described by Taxonomy, which represents about 10% of the described species of life on the planet. Finally, GeneCards (www.genecards.org/) is a very useful source of summary information on a gene of interest, and it provides relevant links to many of the databases mentioned here.

13.5.7 Common File Formats

There are many standard file formats found throughout informatics and many custom file formats unique to bioinformatics. The most simple is delimiter separated values (DSV), in which rows are separated by an end-of-line (EOL) character (generated by the return key). There are system-specific (Windows, Mac, Linux) ways for encoding these characters, although the software often recognizes any method, and its conversion is easy with a good text editor such as Notepad++ or Sublime. Columns are specified by a so-called *delimiting* character. For example, in tab separated value (TSV) files, tabs separate columns; in comma separated value files, CSVs commas are used. One of the strengths of this format is that it can be opened in MS Excel as a spreadsheet or can be relatively easily read and edited in a text file. Another strength is that the delimiter is easily changed and generally may be imported into many programs. Weaknesses include the situation where the data contain a delimiter, effectively splitting the containing cell in two. This can be overcome by surrounding each entry with quotes so that every delimiter character in the data is within quotation marks and so is interpreted correctly, i.e. without special meaning. Also, the DSV format is without any internal structure beyond that of its rows and columns. Sometimes an additional delimiter is used to allow a varying number of one attribute to be linked to another; for example, the gene column of a particular row might contain `“CHID1”` and the probes column might contain `“gnf1h00419_at| gnf1h00420_s_at| gnf1h09948_x_at”`, where a vertical bar “|” separates the data. This can be useful with simple relationships, but it is not commonly supported and, for datasets with more complex relationships it is certainly advisable to use Extensible Markup Language (XML) instead.

XML documents open with an XML declaration, which provides the XML version and character encoding used. The declaration of character encoding indicates which character set was used so it can be correctly read by the recipient. The old web standard—that is, American Standard Code for Information Interchange (ASCII)—is still widely used despite its limited range. To include characters outside of ASCII, such as Greek letters, a Unicode character set, such as UCS Transformation Format—8-bit (UTF-8), is required; it uses multiple bytes to represent additional characters. In XML a parent element may have any number of child elements, which may themselves have any number of child elements and so on. In this case, every entry is surrounded by or ‘wrapped in’ case-sensitive tags. An XML tag is a string of characters itself wrapped in ‘lesser than’ and ‘greater than’ signs (i.e., < >), which respectively indicate the beginning and end of the tag. The second tag also has a forward slash immediately after the “<” to indicate that it is a ‘closing tag’ rather than an ‘opening tag’. This is similar to Hypertext Markup Language (HTML) in structure but not in purpose; moreover, XML tags are defined by the file’s creator rather than by a universal standard. Tags may also have associated attributes that act as classifiers. White space (i.e., spaces, tabs, new lines) outside the tags is meaningless and so can be helpful in formatting the file for easy viewing; this often indicates the nested relationships of the tags. Many good text editors, such as Notepad++ (http://notepad-plus-plus.org) or Sublime (www.sublimetext.com), will automatically color-code files to make them more readable when viewing directly as text. For example:

```
<?xml version="1.0" encoding="ISO-8859-1"?>
<!-- This is a comment, e.g., “Last edited 24/07/2013 – SWR” -->
<genome species=”human”>
        <gene>
                <name>Chitinase Domain Containing 1</name>
                <ID>CHID1</ID>
                <probe type=”Affy”>gnf1h00419_at</probe>
                <probe type=”Affy”>gnf1h00420_s_at</probe>
                <probe type=”Affy”>gnf1h09948_x_at</probe>
                <probe type=”Illumina”>ILMN_2069615</probe>
        </gene>
        <gene>
                <name>NAD Kinase</name>
                <ID>NADK</ID>
        </gene>
</genome>
```

For more complex relationships, there are relational databases. These are collections of tables that follow the relational model [95]. They must be accessed through a relational database management system (RDBMS) such as MySQL. Relational databases comprise a number of tables, but can often be saved into a single file—such as MySQL’s dump file—by their RDBMS and restored on another machine.

Each table must have a primary key: a column with data that uniquely identify each row, or a group of columns whose combination accomplishes this. The latter is known as a compound key because it is made up of several columns. A foreign key, on the other hand, allows records in two tables to be related to one another by a relationship. A 1–n (one-to-many) relationship, as seen in the `gene` and `probe` elements in the XML example, may be described in such a manner. The power of a relational database comes from its ability to support complex m–n (many-to-many) relationships using a third table. As well as data storage in a structure representative of the real world it describes, an RDBMS often has built-in security and Structured Query Language (SQL), subtle variants of which are used by different RDBMSs. Simple SQL queries select certain cells of an attribute from a table where another attribute in that row is equal to a value of interest. More complex queries involve the use of relationships between tables to appropriately join records. The following is a typical, simple example:

```
SELECT name FROM gene WHERE ID=“CHID1”
```

All of the aforementioned file types are common throughout IT. FASTA files are specific to nucleotide and protein sequences and describe either one or multiple sequences. A description line indicated by a “>” serves as a sequence identifier. The sequence follows its corresponding description line. NCBI recommends that each line be restricted to a maximum of 80 characters. Numbers on the left of each column may be present to indicate the position of the first base of that row relative to the first base in the sequence. Spaces can be used to more easily identify the position of each base in the row (e.g., 1 space every 10 bases). File formats such as FASTA are more easily viewed using a monospaced font, where each character occupies the same width across the page such that the columns of letters are aligned. Monospace fonts may also be useful for comparing SQL queries and looking for spelling mistakes that result in errors. The following is an example from the NCBI FASTA specification (www.ncbi.nlm.nih.gov/BLAST/blastcgihelp.shtml):

```
>gi|129295|sp|P01013|OVAX_CHICK GENE X PROTEIN (OVALBUMIN-RELATED)
qikdllvsss tdldttlvlv naiyfkgmwk tafnaedtre mpfhvtkqes kpvqmmcmnn
sfnvatlpae kmkilelpfa sgdlsmlvll pdevsdleri ektinfeklt ewtnpntmek
rrvkvylpqm kieekynlts vlmalgmtdl fipsanltgi ssaeslkisq avhgafmels
edgiemagst gviedikhsp eseqfradhp flflikhnpt ntivyfgryw sp
```

The FASTQ format was developed at the Sanger Institute at the turn of the century and has since become a standard for nucleotide sequencing [96]. There are four line types in FASTQ. The first is the title, which is similar to the description line in FASTA and is indicated by "@" followed by an identifier for the read. Next comes the line for the sequence itself, which, when viewed in a text editor, may spill over if the editor uses a fixed width; however, there should be no EOL characters. The sequence is usually written in uppercase and in standard characters unbroken by white space. The third line begins with "+" and can optionally be followed by the same identifier as in the title line for clarity. The final line contains a length of characters, identical to that in the second line, with each character indicating the quality of the corresponding nucleotide on the second line. There are three FASTQ variants each with different quality scores or encoding of the scores but all of them rely on nonnumeric characters to represent numbers. For example, the original (Sanger) Phred score coding ranged from 0 to 93 and was encoded with ASCII codes 33 (!) through 126 (~)

```
@SRR014849.1 EIXKN4201CFU84 length=93
GGGGGGGGGGGGGGGGCTTTTTTTGTTTGGAACCGAAAGGGTTTTGAATTTCAAACCCTTTTCGGTTTCCAACCTTCCAAAGCAATGCCAATA
+SRR014849.1 EIXKN4201CFU84 length=93
3+&$#"""""""""""7F@71,’";C?,B;?6B;:EA1EA1EA5’9B:?:#9EA0D@2EA5’:>5?:%A;A8A;?9B;D@/=<?7=9<2A8==
```

This range includes upper- and lowercase letters, numbers, and punctuation and excludes white space. One issue with this arrangement is that the "@" and "+" characters are included in the range. This is why it is beneficial to exclude additional EOL characters from FASTQ files to reduce the necessary complexity and the likelihood of errors made by parsing algorithms. Phred is defined as

$$Q_{\mathrm{PHRED}} = -10 \times \log_{10}(P_e)$$

Here "P_e" represents the probability of an erroneous base call. Phred scoring was introduced by the Phred software program, which reads DNA sequencing trace files, "calls" bases, and assigns quality scores. Phred is also used for Illumina FASTQ files from Genome Analyzer Pipeline version 1.3 onward, but with a different range and a different set of ASCII values, so it is easily converted. Software is available to easily convert between these two scoring systems and the scoring system of the third non-Phred FASTQ variant ("Solexa"—the early Illumina score).

GenBank, EMBL, and DDBJ sequence formats follow a similar style and share the taxonomy of NCBI's Taxonomy project and the Feature Table section of each file type for which the formatting is also standardized across the INSDC (www.insdc.org/files/feature_table.html). These formats include annotation of the sequence and its corresponding organism, and they are convenient both for visual inspection in a text editor and for parsing by a computer program. They may describe, for example, a gene or an entire bacterial genome. The EMBL sequence format uses a two-letter code followed by three spaces to begin each line except the sequence lines themselves. The first line always uses the "ID" code for identification of the entry (e.g., accession number, sequence version number, topology.) and no other ID codes for that entry; however, many following line types can be ignored or used several times. The first set of lines annotates the sequence, the organism the sequence is from, pubmed references to relevant papers, and so forth.

A Feature Table follows, identified by `FT` and describing regions or sites of interest. For example, genes and their exons and coding sequences might be notated, using base positions for start and end points for genetic sequences and translated sequences for the corresponding proteins. At the end of the file, the `SQ` (sequence header) line code denotes the header for the sequence. The sequence itself follows, with 60 bases per line and split every ten bases by a space for readability, and ends with `//`. RNA sequences are stored as they exist *in vivo*; that is to say, it is the RNA code, not the corresponding DNA code for the cDNA that was sequenced. The file may be separated by blank "`XX`" lines simply for readability and "`CC`" lines to allow free text comments. The GenBank and DDBJ formats are very similar, but are more self-explanatory because they use entire words such as "`LOCUS`," "`ACCESSION`," and "`FEATURES`" rather than codes and still meet the requirements for parsing in that they are standardized. Additionally, they contain

TABLE 13.4 Summary of Databases and Related Resources

Name	URL	Main Features
Entrez	http://www.ncbi.nlm.nih.gov/gquery	Searches NCBI databases

Table 13.4 contains a listing of bioinformatics-related databases and relevant resources.

GLOSSARY

Alpha helix and beta sheet common secondary protein structures

Amino acid substitution matrix a matrix describing how common each type of amino acid change is, to facilitate scoring of similarity between protein sequences

BLAST a popular algorithm for sequence alignment

Bootstrapping the scoring of a tree or nodes of a tree by resampling and counting outcomes of each pseudoreplicate dataset

***cis* configuration** the two alpha carbon atoms of the connected amino acids on the same side of the peptide bond

Clade/monophyletic group a group in which every descendant of a node is present

Delimiter separated value a plain text file in which rows are separated by EOL characters and columns by a specified delimiter (e.g., tab or comma)

***De novo* structure prediction** the prediction of a protein's structure without the use of templates

Discrete method a method that considers differences in nucleotides directly

Distance method a method that considers only the number of differences between nodes

Dot-matrix a graph representing similarities between two sequences

Gap penalty a penalty on a sequence alignment score, made for the introduction of a gap

Gene ontology a standardized way of classifying genes and their products

Heuristic a "rule-of-thumb" method; not as accurate as, but faster than, an exact method

Homology relation by descent, inferred by similarity. Often used synonymously with 'similarity'

Homology modeling the use of similar protein sequences with known structures in protein modeling

Microarray a surface or "chip" on which a large 2D array of probes is located, used to assay a sample in a high throughput manner

MIM number an ID from OMIM specifying a disease with a genetic component

Molecular evolution the study of the evolution of DNA, RNA, or proteins

Multiple-sequence alignment an alignment of several sequences, often used in phylogenetics and protein modeling

Orthology homology where the sequences have deviated by speciation

Paralogy homology where the sequences have deviated by gene duplication

PDB file a file listing coordinates for the atoms of a protein

Phylogenetics the identification of evolutionary relationships between organisms or between genes

φ and ψ angles rotation angles of certain bonds of a protein backbone

Protein modeling the estimation of a protein's structure using its sequence

***trans* configuration** the two alpha carbon atoms of the connected amino acids are on the opposite sides of the peptide bond

Relational database a database with a complex structure, driven by a relational database management system (RDBMS)

Threading aligning a protein sequence to known structures

Time complexity describes the relationship between the input size n and the time taken for an algorithm to run

XML a text file with a hierarchical structure

14.1 OVERVIEW

The field of pharmacogenomics has grown rapidly over the past several decades, expanding alongside the larger revolution in personalized medicine. This expansion has both led to, and been driven by, an increase in research identifying gene–drug relationships. These associations and relationships are published in diverse articles in a number of journals, and they represent significant additions to our understanding of both pharmacogenetics and pharmacogenomics (PGx).* PharmGKB (www.pharmgkb.org) is funded by the National Institutes of Health (NIH) and the National Institute of General Medical Sciences (NIGMS), and includes a publicly available online knowledgebase that

1. Annotates, aggregates, and integrates reported study results and stores this information in a systematic and useful manner.
2. Contributes to clinical pharmacogenomic implementation projects.
3. Enables consortia, both data-centric and knowledge-centric, to address pharmacogenomic questions and develop drug-dosing guidelines.

The foundation of PharmGKB consists of its vast collection of PGx study results, and it is a valuable resource for clinicians and researchers across broad areas of science and medicine. This wealth of data also places PharmGKB in the unique position of being able to recognize clinically relevant results. Creating high-level annotations that identify variant–drug associations with a preponderance of supporting evidence provides the underlying knowledge needed for clinical pharmacogenomic implementation. PharmGKB's mission goes beyond the acquisition and dissemination of knowledge to include co-leading the Clinical Pharmacogenetics Implementation Consortium (CPIC), which provides drug-dosing guidelines based on an individual's genotype. This chapter describes the variety of knowledge and knowledge-based activities available in PharmGKB and how the knowledgebase can be easily used to find out more about PGx associations of interest.

---

* Pharmacogenetics is the study of genetic influence on drug response, usually involving one or two genes. Pharmacogenomics is the study of how genomic variation influences drug response across the genome. Although technically distinct, we use the term *pharmacogenomics* (PGx) throughout this chapter to represent both.

FIGURE 14.1 **PharmGKB homepage.** From the PharmGKB homepage, all knowledge on PharmGKB can be easily accessed, either by searching for a variant, gene, drug, disease, or phenotype of interest, or through direct links provided at the bottom of the page. Under the "Clinically-Relevant PGx summaries" heading on the left, links are provided to high-level clinical annotations, drug-dosing guidelines, and drug labels. Under "PGx Research" on the right, links are provided to VIP summaries and pathways. A rotating box in the center provides updates on the latest information added to the website.

14.2 THE PHARMGKB WEBSITE

The PharmGKB website contains several principal types of knowledge, which are discussed in the following sections. These include variant annotations, clinical annotations, very important pharmacogene (VIP) summaries, pathways, dosing guidelines, and drug labels. The PharmGKB homepage can be seen in Figure 14.1. From this page, users can search for variants, genes, drugs, and diseases or phenotypes of interest, or access the different types of PharmGKB knowledge through direct links at the bottom of the page.

A visual summary of the various types of information and how they are integrated in PharmGKB is provided in the PharmGKB Knowledge Pyramid (Figure 14.2). Primary PGx literature represents the basis of all knowledge created on PharmGKB. Through both manual curation and natural-language processing (NLP) (see Section 14.7 for more on the latter), PharmGKB extracts information from this literature and provides it on the website in the form of variant annotations, where each variant annotation describes an association between a single genetic variant and a drug phenotype as found in a publication. FIGURE 14.2 **The PharmGKB Knowledge Pyramid.** The PharmGKB Knowledge Pyramid is a visual representation of the various types of information available on PharmGKB. Primary pharmacogenomics literature forms the base, from which PharmGKB curators extract relevant PGx information ("Knowledge Extraction") and create variant annotations, VIP summaries, and pathways ("Knowledge Annotation, Aggregation & Integration"). Clinical annotations build on variant annotations ("Clinical Interpretation"). Clinical implementation, shown at the top of the pyramid, represents an important end goal for PharmGKB.

primary literature information, PharmGKB curators can also create original materials such as VIP summaries and drug-centered pathways. Clinical annotations build further on variant annotations and are clinically inclined and evidence-rated summaries of all variant annotations that discuss a particular variant and drug phenotype. PharmGKB's involvement in clinical implementation projects and data-centric consortia is represented at the top level of the pyramid, as implementation is supported by all other knowledge in PharmGKB. Through the creation of its various materials, PharmGKB is able to push PGx information upward from original publications toward potential clinical implementation.

Throughout this chapter, we primarily use the *CYP3A5* single-nucleotide polymorphism (SNP) rs776746 (also known as *CYP3A5**3) as an example variant, as well as the immunosuppressant tacrolimus as an example drug, to illustrate the types of knowledge a user can ascertain from the PharmGKB website. The rs776746 C allele results in a nonfunctional CYP3A5 protein [1] and since CYP3A5 is responsible for metabolizing tacrolimus, [2] this variant and drug represent a PGx association of interest.

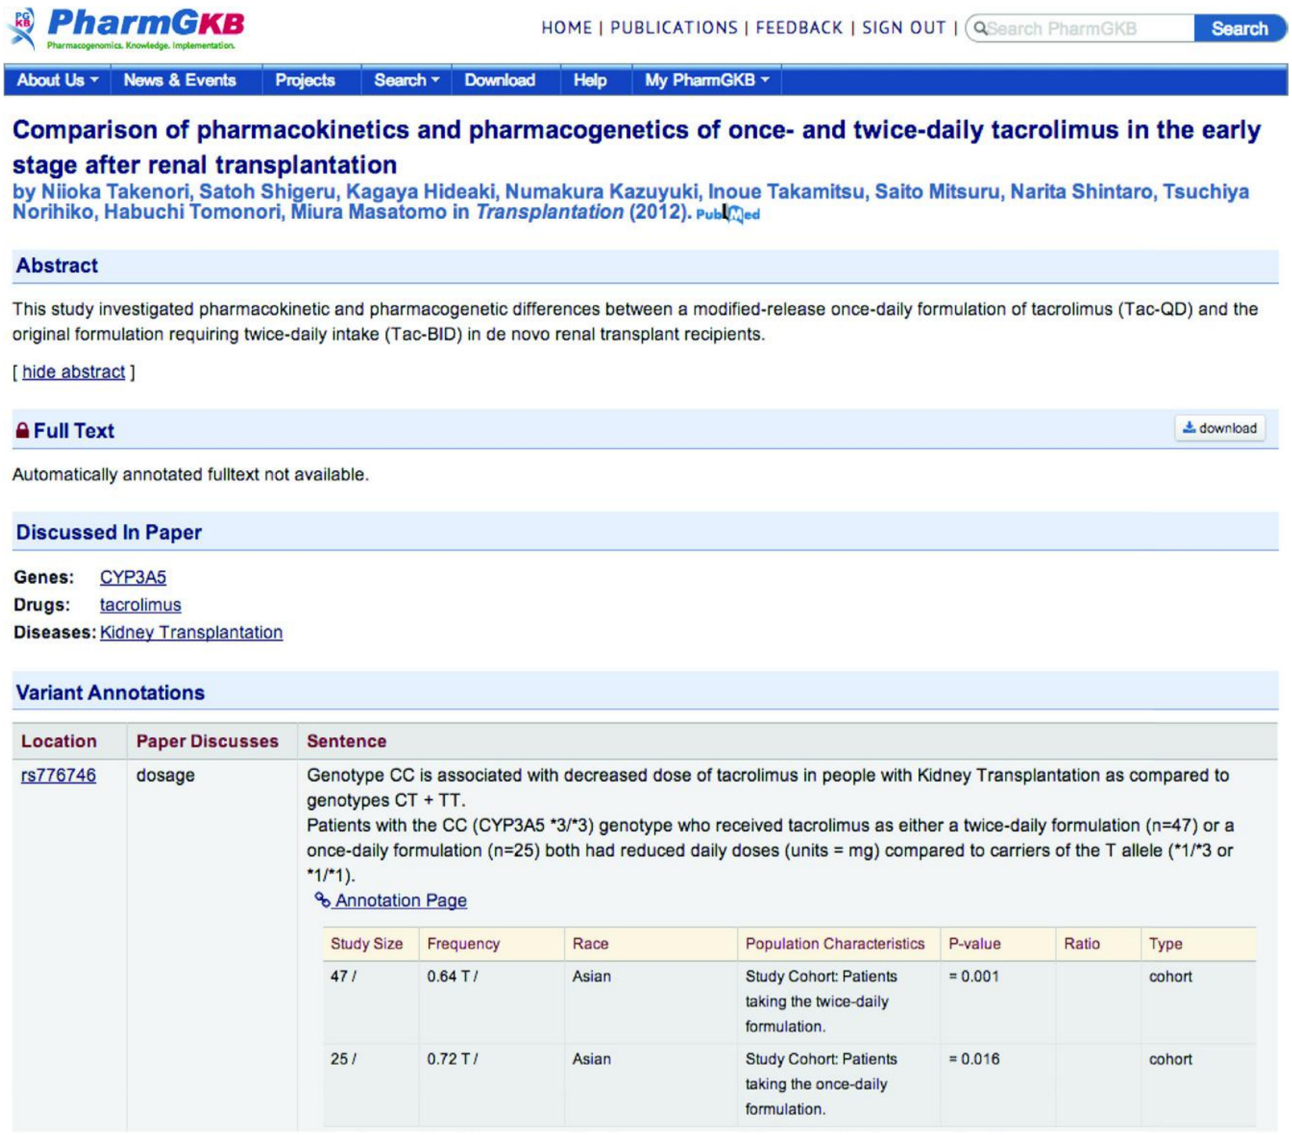
14.3 VARIANT ANNOTATIONS

Variant annotations are core components of PharmGKB; they are summaries describing how a particular genetic variant is associated with a drug response, such as efficacy or toxicity, as reported in a single publication. To create these summaries, PharmGKB curators manually review past and current literature and add any studies containing relevant pharmacogenomic information to the knowledgebase. While PharmGKB aims to capture as many studies as possible, complete coverage is not feasible given the volume of literature and resources needed for manual curation. However, ongoing work using NLP will greatly aid these efforts in the future (see Section 14.7).

An example variant annotation is shown in Figure 14.3. Information about the publication, including an abstract, appears at the top of the page and annotations appear at the bottom. In this particular example, the publication of interest is a 2012 study by Niioka et al. [3]. Here, the authors found that the daily dose of tacrolimus was lower in patients with the rs776746 CC genotype as compared to those with the CT or TT genotype. Since this association is a relevant PGx finding, a variant annotation was created for it.

Variant annotations can be created for positive or negative results and consist of a summary describing the study results as well as other important information such as study size, allele frequencies, p-values, and other statistical results. Annotations are written for variants other than SNPs, including copy number variants (CNVs) and insertions and deletions (indels). Additionally, they can be submitted on haplotypes, and full haplotype spreadsheets for certain genes are available for download on the PharmGKB site. The term "variant" is used throughout this chapter to indicate these different types of variants as well as haplotypes. PharmGKB includes annotations on many primary studies, including genome-wide association studies (GWAS), clinical trials, and functional *in vitro* studies. Additional information about variant annotations can be found in the review by McDonagh et al. [4].

For brevity, only one annotation is shown in Figure 14.3. However, Niioka et al. found other pharmacokinetic results in their study that did not directly pertain to dose. These were added as additional, separate annotations and appear below the example annotation on the original webpage. A research article annotated in PharmGKB can have as many



Comparison of pharmacokinetics and pharmacogenetics of once- and twice-daily tacrolimus in the early stage after renal transplantation

by Niioka Takenori, Satoh Shigeru, Kagaya Hideaki, Numakura Kazuyuki, Inoue Takamitsu, Saito Mitsuru, Narita Shintaro, Tsuchiya Norihiko, Habuchi Tomonori, Miura Masatomo in *Transplantation* (2012).

Abstract

This study investigated pharmacokinetic and pharmacogenetic differences between a modified-release once-daily formulation of tacrolimus (Tac-QD) and the original formulation requiring twice-daily intake (Tac-BID) in de novo renal transplant recipients.

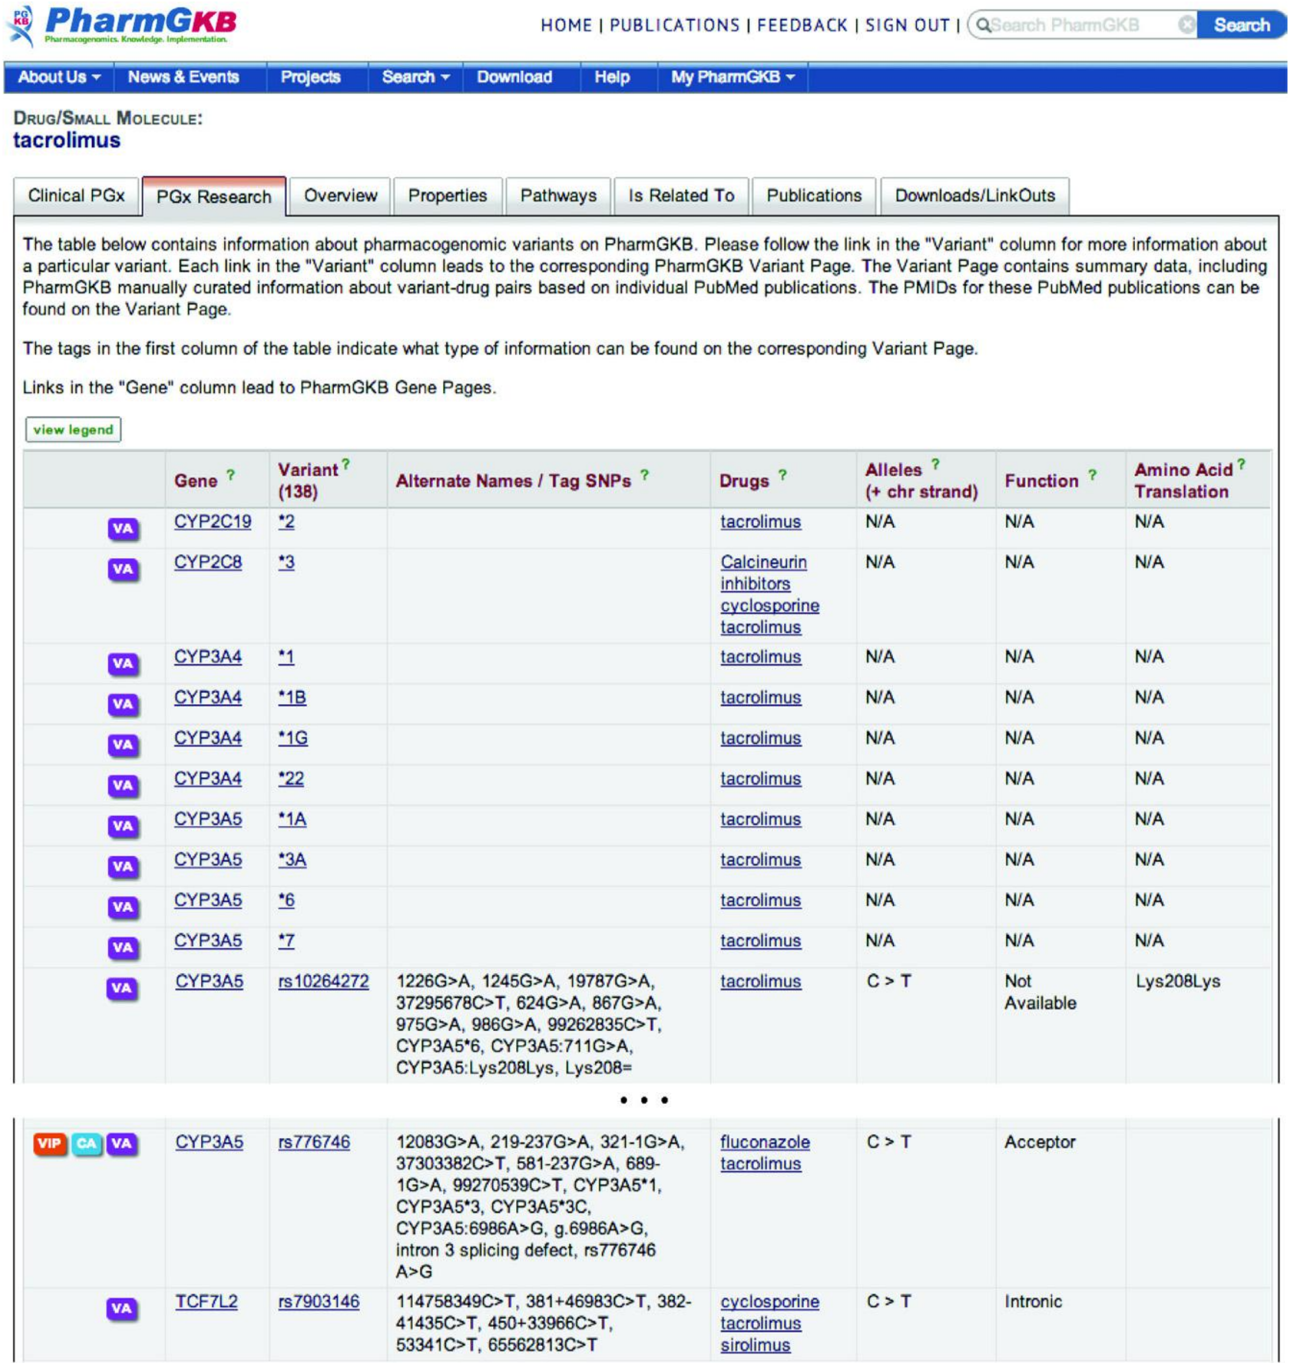
FIGURE 14.3 **PharmGKB variant annotation.** Annotations are created on individual publications and consist of standardized summaries of any pharmacogenomic results found in the published study results. Multiple annotations can be created for a single study if multiple associations are found. Information about the publication, including an abstract, is shown at the top of the page; annotations appear at the bottom. The full annotation can be viewed at www.pharmgkb.org/pmid/23073468.

annotations as the different associations found. The enormous number of annotated publications on the PharmGKB website, combined with the varied number of individual annotations on each publication, leads to a large amount of data, which PharmGKB keeps organized using several methods. Every variant annotation contains one summary sentence written in a highly standardized format; in Figure 14.3 that sentence is the first one under the "Sentence" column in the Variant Annotations section. Every annotation added to PharmGKB is entered using a curator annotation tool developed by the PharmGKB staff, restricting text to a predefined format. This allows results to be easily compared and contrasted between or within studies. However, space for free text is provided below the standardized sentence, in case further elaboration on results is necessary (as seen in Figure 14.3, where the sentence in the second paragraph is free text).

PharmGKB also keeps its information organized by storing and structuring data around four specific entities: variants, genes, drugs, and diseases or phenotypes. Every variant annotation contains a variant, and most will include drug information. Annotations also include a disease or phenotype if appropriate; examples include Stevens-Johnson syndrome, which is often seen in annotations describing



DRUG/SMALL MOLECULE:
tacrolimus

The table below contains information about pharmacogenomic variants on PharmGKB. Please follow the link in the "Variant" column for more information about a particular variant. Each link in the "Variant" column leads to the corresponding PharmGKB Variant Page. The Variant Page contains summary data, including PharmGKB manually curated information about variant-drug pairs based on individual PubMed publications. The PMIDs for these PubMed publications can be found on the Variant Page.

The tags in the first column of the table indicate what type of information can be found on the corresponding Variant Page.

Links in the "Gene" column lead to PharmGKB Gene Pages.

FIGURE 14.4 **PharmGKB drug page for tacrolimus.** Different tabs at the top under "tacrolimus" provide different information about this drug. The "PGx Research" tab provides a table of variants and corresponding genes that have been associated with that drug in variant annotations. Colorful icons in the far left column indicate whether other available PharmGKB resources discuss that particular variant and a drug, such as VIPs (orange "VIP") or clinical annotations (blue "CA"); clicking "view legend" explains the meaning of each icon. The "Clinical PGx" tab provides information about the drug from other PharmGKB sources, such as clinical annotations or dosing guidelines. Other tabs provide additional information about the drug ("Overview"; "Properties") and lists of publications with annotations that include it ("Publications").

an adverse reaction to allopurinol in *HLA-B**58:01 carriers, and neutropenia, which is typically used in annotations describing side effects of irinotecan in *UGT1A1**28 carriers. Standardized vocabularies are used for these entities, ensuring regularization of terms across all annotations. PharmGKB sources several outside databases for these vocabularies. Variant annotations are typically created for a specific reference SNP identification (rsID) as defined by the National Center for Biotechnology Information (NCBI) SNP database (dbSNP) [5]. For haplotypes, PharmGKB curates information from the literature or from nomenclature resources such as the Human Cytochrome P450 (CYP) Allele Nomenclature Database [6]; the UDP-Glucuronosyltransferase Alleles Nomenclature page [7]; and the HLA Nomenclature resource [8]. Gene symbols come from the HUGO Gene Nomenclature Committee (HGNC) [9]; drug, compound, or substance information comes from DrugBank [10], WHO's Anatomical Therapeutic Chemical (ATC) classification system, [11] or PubChem [12]. Disease and phenotype ontologies are taken from the National Library of Medicine's Medical Subject Headings (MeSH) browser [13].

PharmGKB curators can add terms to each of these vocabularies or ontologies if necessary. rsIDs, genes, drugs and diseases, or phenotypes present in these pre-existing vocabularies have their own pages on PharmGKB. When a variant annotation is created that includes entities from these sources, the relevant page is populated with information from that annotation. Additionally, each time entities in these vocabularies are discussed together in a variant annotation, they are stored as a relationship in the database. This creates a network of connections throughout PharmGKB that can be used for further research and discovery. PharmGKB is currently working on a visualization prototype for this data (see Section 14.7), but any registered user can download a file of these relationships from PharmGKB and use them in further research.

Organizing information around the four entities makes finding information on PharmGKB straightforward. Users can search for a gene, drug, disease, or variant of interest and be taken to its specific page, where all PharmGKB knowledge on the entity is accumulated. This includes variant annotation data as well as information from clinical annotations, VIP summaries, pathways, dosing guidelines, and drug labels. Information from variant annotations is amassed under the "PGx Research" tab on a variant, gene, drug, or disease page. As an example, the drug page for tacrolimus is shown in Figure 14.4. A table lists the variants and corresponding genes that have been associated with that drug in variant annotations, and rs776746 and tacrolimus can be seen near the bottom of the figure. Colorful icons in the far left column indicate whether a variant and drug appear together in other PharmGKB resources, such as a clinical annotation (indicated by the blue "CA" icon) or a VIP (the orange "VIP" icon). Icons also exist for pathways, dosing guidelines, and drug labels, and more information about them can be found by clicking the "view legend" button on any drug, gene or disease page.

Gene pages are similar to drug pages, except that only variants from that gene are listed and all associated drugs are shown. Disease or phenotype pages can be extensive since they are not filtered by a drug or gene, and they list every annotation that mentions the disease or phenotype. Variant pages are slightly different, providing a table of all publications that have annotations discussing that variant, organized by PubMed ID (PMID). An image of the variant page for rs776746 can be seen in Figure 14.5; the annotations on the study by Niioka et al. (PMID 23073468) can be seen at the bottom of the figure. The table provides information from each annotation, including associated drug, standardized sentence, statistical significance, p-value, study size, and race. It is also filterable and sortable. Clicking on the PMID link opens the publication page to view the original annotation.

PharmGKB variant annotations can be used individually, such as by students interested in a particular PGx study, or in bulk, such as by researchers who wish to conduct further pharmacogenomic analyses. In addition to their consistency, quality, and volume, variant annotations are also valuable because they are easily aggregated. Annotations that discuss the same variant and drug response can be readily accumulated, allowing for assessment of clinical relevance. This is important from a clinical implementation perspective, and PharmGKB takes advantage of this ability through the creation of clinical annotations.

14.4 CLINICAL ANNOTATIONS

Clinical annotations are summaries of PharmGKB's literature evidence for a particular variant–drug association. Recall that every page for a specific variant includes a table of all the publications that include the variant in an annotation, as well as the associated drug and other relevant information. A user can look at this page and filter the table to see whether there are consistent associations between a variant and a drug or class of drugs. However, PharmGKB condenses this information in a concise, evidence-rated summary known as a clinical annotation. Clinical annotations combine all of the studies that show a relationship between a variant and a drug phenotype (or closely related phenotypes) and bring them together on one page. Each clinical annotation provides a short summary of the relationship for each genotype (or haplotype) compared to other genotypes, as well as a list of every study used as evidence for the association; this allows users to view the exact results supporting a clinical annotation.

More information on clinical annotations, as well as on why PharmGKB reports relationships relative to other genotypes, can be found in the paper by Whirl-Carrillo et al. [14]. Multiple studies have found an association between rs776746 and tacrolimus dose and metabolism; the clinical annotation for this association can be seen in Figure 14.6. The genotype-based summary is at the top of the page, and a selection of the evidence list is at the bottom; the study by Niioka et al. is evidence number 10. Metabolism and dose are closely linked, but studies that discuss disparate phenotypes receive separate clinical annotations. For instance, rs776746 and tacrolimus have additional clinical annotations for associations with nephrotoxicity and transplant rejection.

Variant Annotations

PharmGKB variant annotations provide information about variant-drug pairs or variant-disease pairs based on individual PubMed publications. Each annotation represents information from a single paper and the goal is to report the information that the author states, not an interpretation of the paper. The PMID for supporting PubMed publications is found in the "Evidence" field.

Information presented, including study size, allele frequencies and statistics is taken directly from the publication. However, if the author does not correct p-values in cases of multiple hypotheses, curators may apply a Bonferroni correction. Curators attempt to report study size based on the actual number of participants used for the calculation of the association statistics, so the number may vary slightly from what is reported in the abstract of the paper. OMB Race Category information is derived from the paper and mapped to standardized categories. Category definitions may be found by clicking on the "OMB Race Category" link.

PMID	Drug	Sentence	Significance	pValue	# of Cases	Race
17510208	irinotecan	Genotype CC is not associated with Neutropenia when treated with irinotecan in people with Colonic Neoplasms as compared to genotype TT.	no	0.426	92

FIGURE 14.5 **Variant page for rs776746.** Information about the variant, such as alleles and alternate names, is provided at the top of a variant annotation page. Under the "PGx Research" tab, a table is provided that lists each publication (by PMID) that has an annotation using that variant. Additional information from the study is also provided, such as p-value and study size. Clicking on the PMID opens the original annotation. Additional tabs provide information similar to that discussed in Figure 14.4. Here only five annotations that include rs776746 are shown, although many more exist for this variant. See www.pharmgkb.org/rsid/rs776746 for a full list.

After writing the summaries and viewing the supporting evidence, curators assign every clinical annotation a level of evidence, giving a measure of the confidence in the association. Levels of evidence are based on several criteria, including study sizes, p-values, odds ratios, and replication of the association. Negative results also play a critical role in this determination. An overview of the meaning behind the various levels of evidence can be seen in Figure 14.7 and is discussed in the paper by Whirl-Carrillo et al. [14]. This information can also be accessed by clicking the green "what's this" button next to the evidence level (see Figure 14.6).

Many variant annotations on PharmGKB are singular, meaning that there is no replication of an association between that genetic variant and a drug response. These studies are assigned an evidence level of 3. Clinical

CC	Patients with the CC genotype (CYP3A5*3/*3) and recipients of a transplantation who are treated with tacrolimus may have decreased metabolism of tacrolimus resulting in increased exposure, and may require a lower dose as compared to patients with the CT or TT genotype. Other genetic and clinical factors may also influence a patient's tacrolimus dose requirement.
CT	Patients with the CT genotype (CYP3A5*1/*3) and recipients of a transplantation who are treated with tacrolimus may have increased clearance of tacrolimus resulting in decreased exposure, and may require a higher dose as compared to patients with the CC genotype. Other genetic and clinical factors may also influence a patient's tacrolimus dose requirement.
TT	Patients with the TT genotype (CYP3A5*1/*1) and recipients of a transplantation who are treated with tacrolimus may have increased clearance of tacrolimus resulting in decreased exposure, and may require a higher dose as compared to patients with the CC genotype. Other genetic and clinical factors may also influence a patient's tacrolimus dose requirement.

1. Genotypes CT + TT are associated with increased clearance of tacrolimus in people with liver transplantation as compared to genotype CC. Patients with the CT + TT (CYP3A5 *1/*3 + *1/*1) genotypes had decreased tacrolimus trough concentrations (C0) and dose-adjusted trough concentrations (C0/D) on day 7 after transplantation, as compared to CC (*3/*3) homozygotes. No significant differences were seen on days 3, 14, 30 or 90.

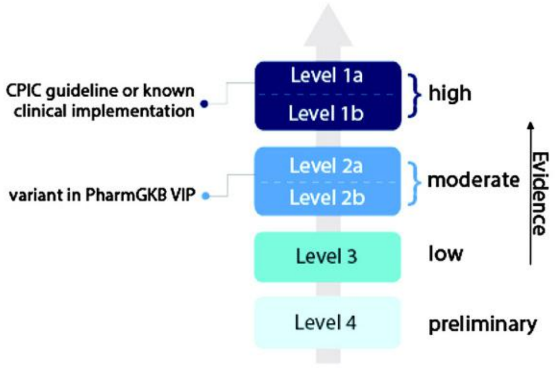
FIGURE 14.6 **Clinical annotation for rs776746 in *CYP3A5* and tacrolimus.** Clinical annotations can be found under the "Clinical PGx" and "Clinical Annotation" tabs on the variant, gene, or drug page. They consist of short genotype-based summaries of the literature evidence behind a variant–drug association. All clinical annotations are given a level of evidence that indicates the strength of the association. Supporting evidence behind the literature summary is given in a drop-down list below the text.

annotations are not created if associations between a variant and drug phenotype are exclusively negative. However, as more literature is published, additional studies may accumulate that discuss that particular association, with either positive or negative results.

PharmGKB curators periodically reassess the level of evidence of clinical annotations, adding recently created variant annotations as support. Variant–drug interactions can therefore move up or down through the levels, giving an indication of whether an association may be clinically



Level 1A

Annotation for a variant-drug combination in a CPIC or medical society-endorsed PGx guideline, or implemented at a PGRN site or in another major health system.

Level 1B

Annotation for a variant-drug combination where the preponderance of evidence shows an association. The association must be replicated in more than one cohort with significant p-values, and preferably will have a strong effect size.

Level 2A

Annotation for a variant-drug combination that qualifies for level 2B where the variant is within a VIP (Very Important Pharmacogene) as defined by PharmGKB. The variants in level 2A are in known pharmacogenes, so functional significance is more likely.

Level 2B

Annotation for a variant-drug combination with moderate evidence of an association. The association must be replicated but there may be some studies that do not show statistical significance, and/or the effect size may be small.

Level 3

Annotation for a variant-drug combination based on a single significant (not yet replicated) or annotation for a variant-drug combination evaluated in multiple studies but lacking clear evidence of an association.

Level 4

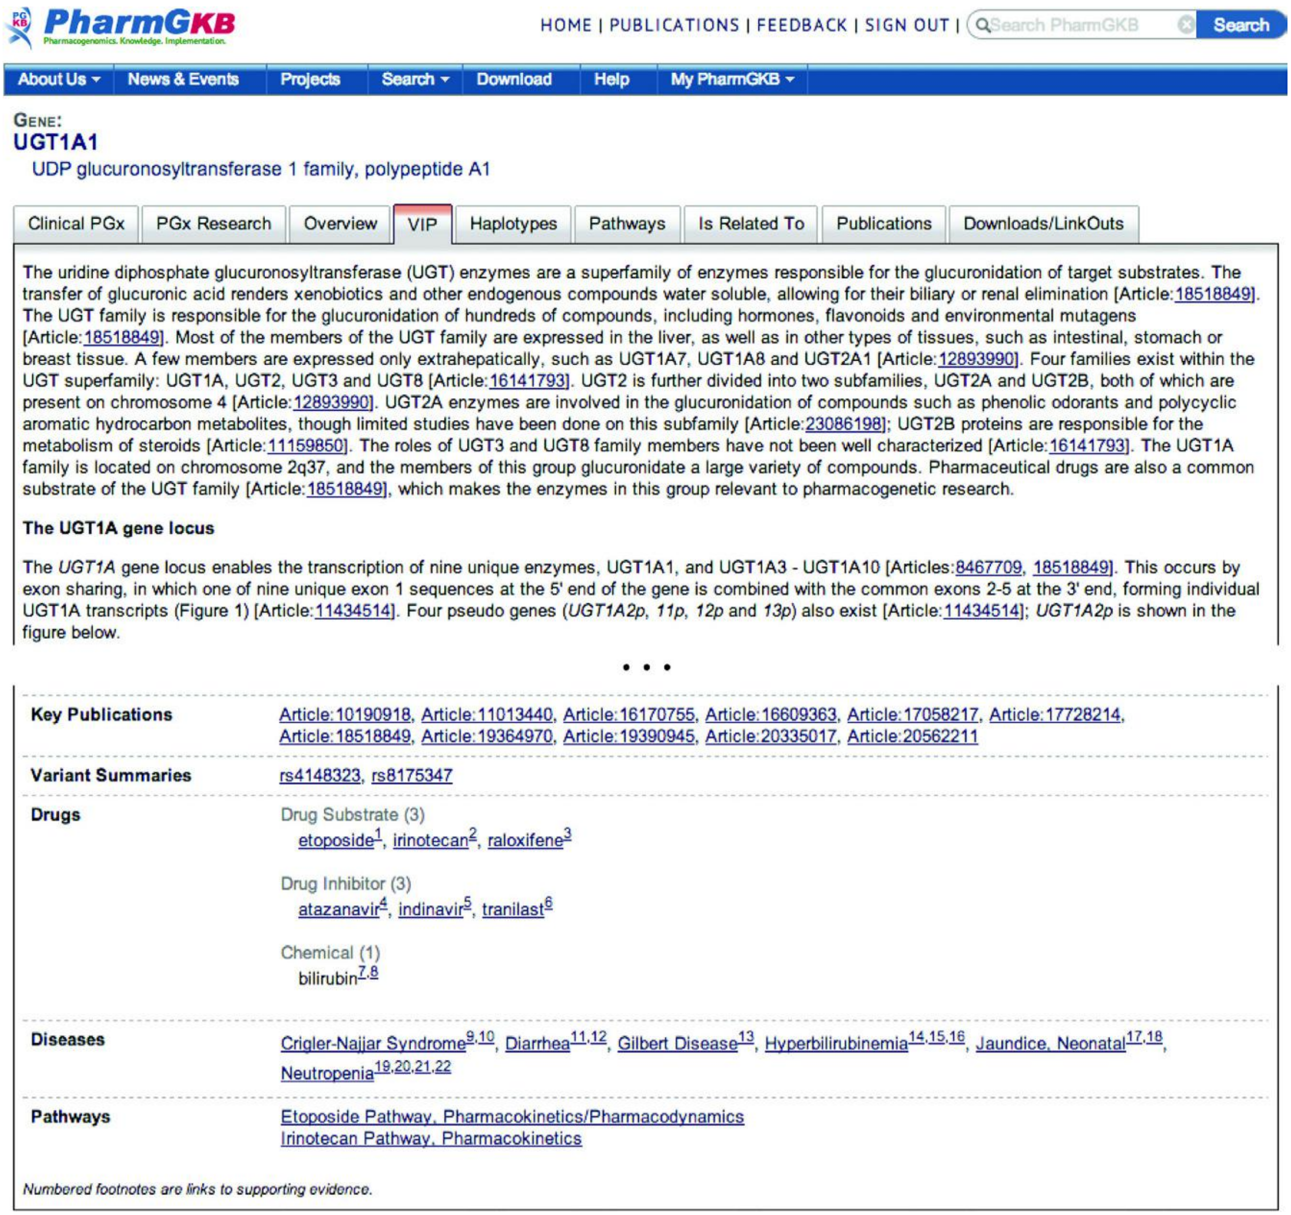
Annotation based on a case report, non-significant study or in vitro, molecular or functional assay evidence only.

FIGURE 14.7 **PharmGKB levels of evidence for clinical annotations.** Assigning levels of evidence to an association is a critical function of PharmGKB curators. Internal guidelines for assigning levels of evidence provide consistency for curators and transparency for users. Many annotations are unique and therefore are assigned a level of 3. However, as annotations accumulate for a particular variant–drug response, the level of evidence may change.

relevant. Associations that show level 1B evidence are of particular importance to PharmGKB, as they likely have potential for clinical implementation; level 1A indicates that implementation is already occurring or that a PGx guideline exists for that variant and drug. The association between rs776746 and tacrolimus dose and metabolism is assigned an evidence level of 1B, and PharmGKB has begun work with the Clinical Pharmacogenentics Implementation Consortium (CPIC) [15] to develop dosing guidelines for the drug based on the rs776746 genotype. PharmGKB keeps a close eye on all associations that show high levels of evidence, and the resource often works closely with consortia on guidelines or implementation for associations with strong supporting evidence. As with variant annotation data, registered users who submit a request can download a file of all PharmGKB clinical annotation data if they wish to pursue further research using this information. Indeed, various implementation research programs, such as the 1200 Patients Project, have used clinical annotations to help decide which PGx variants to include in their studies [16].

14.5 VIPS AND PATHWAYS

In addition to variant and clinical annotations, PharmGKB creates informational materials about genes and drugs of particular pharmacogenomic interest. VIPs are overviews of important genes involved in drug response that typically include background information on the gene and any disease associations, as well as in-depth information on the gene's pharmacogenetics. *CYP3A5*, the gene that contains rs776746, has a VIP; it is part of the *CYP3A* gene family, whose protein members facilitate the elimination of a



GENE:
UGT1A1
UDP glucuronosyltransferase 1 family, polypeptide A1

The uridine diphosphate glucuronosyltransferase (UGT) enzymes are a superfamily of enzymes responsible for the glucuronidation of target substrates. The transfer of glucuronic acid renders xenobiotics and other endogenous compounds water soluble, allowing for their biliary or renal elimination [Article:18518849]. The UGT family is responsible for the glucuronidation of hundreds of compounds, including hormones, flavonoids and environmental mutagens [Article:18518849]. Most of the members of the UGT family are expressed in the liver, as well as in other types of tissues, such as intestinal, stomach or breast tissue. A few members are expressed only extrahepatically, such as UGT1A7, UGT1A8 and UGT2A1 [Article:12893990]. Four families exist within the UGT superfamily: UGT1A, UGT2, UGT3 and UGT8 [Article:16141793]. UGT2 is further divided into two subfamilies, UGT2A and UGT2B, both of which are present on chromosome 4 [Article:12893990]. UGT2A enzymes are involved in the glucuronidation of compounds such as phenolic odorants and polycyclic aromatic hydrocarbon metabolites, though limited studies have been done on this subfamily [Article:23086198]; UGT2B proteins are responsible for the metabolism of steroids [Article:11159850]. The roles of UGT3 and UGT8 family members have not been well characterized [Article:16141793]. The UGT1A family is located on chromosome 2q37, and the members of this group glucuronidate a large variety of compounds. Pharmaceutical drugs are also a common substrate of the UGT family [Article:18518849], which makes the enzymes in this group relevant to pharmacogenetic research.

The UGT1A gene locus

The *UGT1A* gene locus enables the transcription of nine unique enzymes, UGT1A1, and UGT1A3 - UGT1A10 [Articles:8467709, 18518849]. This occurs by exon sharing, in which one of nine unique exon 1 sequences at the 5' end of the gene is combined with the common exons 2-5 at the 3' end, forming individual UGT1A transcripts (Figure 1) [Article:11434514]. Four pseudo genes (*UGT1A2p*, *11p*, *12p* and *13p*) also exist [Article:11434514]; *UGT1A2p* is shown in the figure below.

FIGURE 14.8 **VIP for the gene *UGT1A1*.** VIPs are summaries of genes of particular pharmacogenomic interest. The UGT1A1 protein is part of the UGT family and is involved in the glucuronidation of a wide variety of pharmaceuticals, making it relevant to PGx research. VIPs consist of textual summaries (a portion of which is shown in the figure), as well as lists of key publications and drugs and diseases that are relevant to the gene. Any pathways in which the gene appears are also listed. VIPs, if available, can be accessed through the "VIP" tab at the top of the page.

large percentage of drugs. Other examples of VIPs include *G6PD*, *TMPT*, and *UGT1A1*; a list of all PharmGKB VIPs can be found on the website. Individual VIPs, if available, can be accessed through the relevant PharmGKB gene page.

Figure 14.8 is an example of a VIP for the gene *UGT1A1*. A portion of the textual summary is shown, as is the bottom of the page, where key publications are cited. VIPs are intended for users wishing to gain a better understanding of a gene, and key publications represent references that provide this for the gene and its pharmacogenetics. An overview of the drugs and diseases relevant to the gene are also given at the bottom of the summary, with links to their corresponding PharmGKB pages.

VIPs often include independent summaries for the important PGx variants within a gene. If available, these can be accessed through the "Variant Summaries" row at the bottom of the VIP page (see Figure 14.8). An example of a variant summary for rs8175347 in *UGT1A1* (also known as *UGT1A1**28) is shown in Figure 14.9. VIP variant summaries complement the clinical annotations for a variant by providing more background information, such as the biological effect of the allele on the gene, allele frequencies,

UGT1A1*28
(TA)7 repeat

*UGT1A1*28* consists of seven thymine-adenine (TA) repeats within the promoter region, which lead to impairment of gene transcription and a decrease in transcriptional activity by approximately 70% [Articles:7565971, 12181419]. It occurs with a frequency of 0.26 - 0.31 in Caucasians, and 0.42 - 0.56 in African Americans, and only 0.09 - 0.16 in Asian populations [Articles:10591539, 9653159].

The allele has been linked to side effects from irinotecan treatment such as neutropenia and diarrhea, though some studies have seen negative results for both phenotypes [Articles:15709193, 15007088, 15280927]. In 2004 the US Food and Drug Administration (FDA) recommended on their drug label that homozygotes for the *28 allele receive a lower starting dose of irinotecan. A 2010 meta-analysis of 1998 patients found that the **28/*28* genotype was associated with an increased risk of neutropenia for patients taking low (<150 mg/m2), medium (150-250 mg/m2) and high (>250 mg/m2) doses of the drug, compared to those with other genotypes [Article:20562211]. However, an earlier meta-analysis found that patients with the **28/*28* genotype had a higher risk of neutropenia compared to the other genotypes only at medium or high doses; *UGT1A1*28/*28* patients taking low doses had a similar risk to wild-type homozygotes [Article:17728214]. Indeed, the Dutch Pharmacogenetics Working Group recommends only adjusting irinotecan dose for *28 homozygotes if the dose is greater than 250 mg/m2, upon which it should be reduced by 30% to avoid complications from neutropenia or diarrhea. Below this, no recommendations have been made (see guidelines).

FIGURE 14.9 **VIP Variant summary for rs8175347.** VIP variant summaries are for variants that show important PGx associations; they are often created in tandem with VIPs. If available, these overviews can be accessed through the "VIP" tab on a variant page. They provide information about the variant, including allele frequencies and a detailed overview of the literature evidence for any drug–response associations.

and a more detailed overview of the literature evidence for that variant. Variant summaries can be found on the relevant variant's page.

VIP genes are chosen through a variety of means. These genes include those that are referred to on U.S. Food and Drug Administration (FDA) drug labels or that appear as part of important pharmacogenomic developments discussed in recent literature. Additionally, VIPs can be created if a curator notes that the gene is associated with a large number of variant annotations or is part of high-level clinical annotations.

PharmGKB pathways are illustrations detailing the pharmacokinetics or pharmacodynamics of a PGx-relevant drug; they demonstrate physiological interactions between the drug and various proteins (represented as the corresponding genes in PharmGKB) in cells. Figure 14.10 shows the pharmacokinetic pathway created for the metabolism of tacrolimus and cyclosporine. These two drugs, both immunosuppressants, have identical pharmacokinetics and so appear together in the pathway.

Other pathways on PharmGKB include warfarin pharmacokinetics and pharmacodynamics, and tamoxifen pharmacokinetics. A list of all PharmGKB pathways can be found on the website. PharmGKB recognizes that proteins are responsible for metabolizing or transporting drugs; however, these products are stored as genes in the knowledgebase, and so the genes coding for various proteins are used in pathways. In Figure 14.10, *CYP3A5* (coding for its eponymous enzyme) is shown metabolizing tacrolimus, while *ABCB1* (coding for P-glycoprotein) is shown transporting the drug across the intestinal cell membrane. PharmGKB pathways are interactive—drugs and genes that appear on them are clickable and link to their respective pages. Pathways can thus be accessed from the relevant drug or gene pages. Additionally, pathways are downloadable in multiple formats, including BioPax, to allow the information stored in them to be easily used in different ways.

PharmGKB pathways are manually created by curators after an extensive literature review, and the connections on the pathway in the online version of the figure are supported

FIGURE 14.10 **PharmGKB tacrolimus and cyclosporine pharmacokinetics pathway.** Pathways detail either the pharmacokinetics or pharmacodynamics of a drug of interest. Genes that code for proteins involved in a drug's pharmacology are shown on the pathway, which always includes accompanying text that provides more information about the pharmacology and pharmacogenomics of the drug. They are excellent starting points for learning more about a PGx-relevant medication.

by specific literature citations; these can be found under the "Components" tab on the pathway page (see Figure 14.10). Pathway images are accompanied by text that provides more general information about the drug, as well as a discussion of its pharmacokinetics or pharmacodynamics and pharmacogenomics. Pathways are an excellent starting point for users who want to learn more about a drug, and PharmGKB pathways are often used in lectures and book chapters. Pathways are created for drugs that have enough literature-based evidence to support graphical, gene-based representations of the pharmacology of a drug. Both pathways and VIPs are often created in collaboration with experts in the field and are typically published in the journal *Pharmacogenetics and Genomics*.

14.6 CLINICAL IMPLEMENTATION: CONSORTIA, CPIC, AND DOSING GUIDELINES

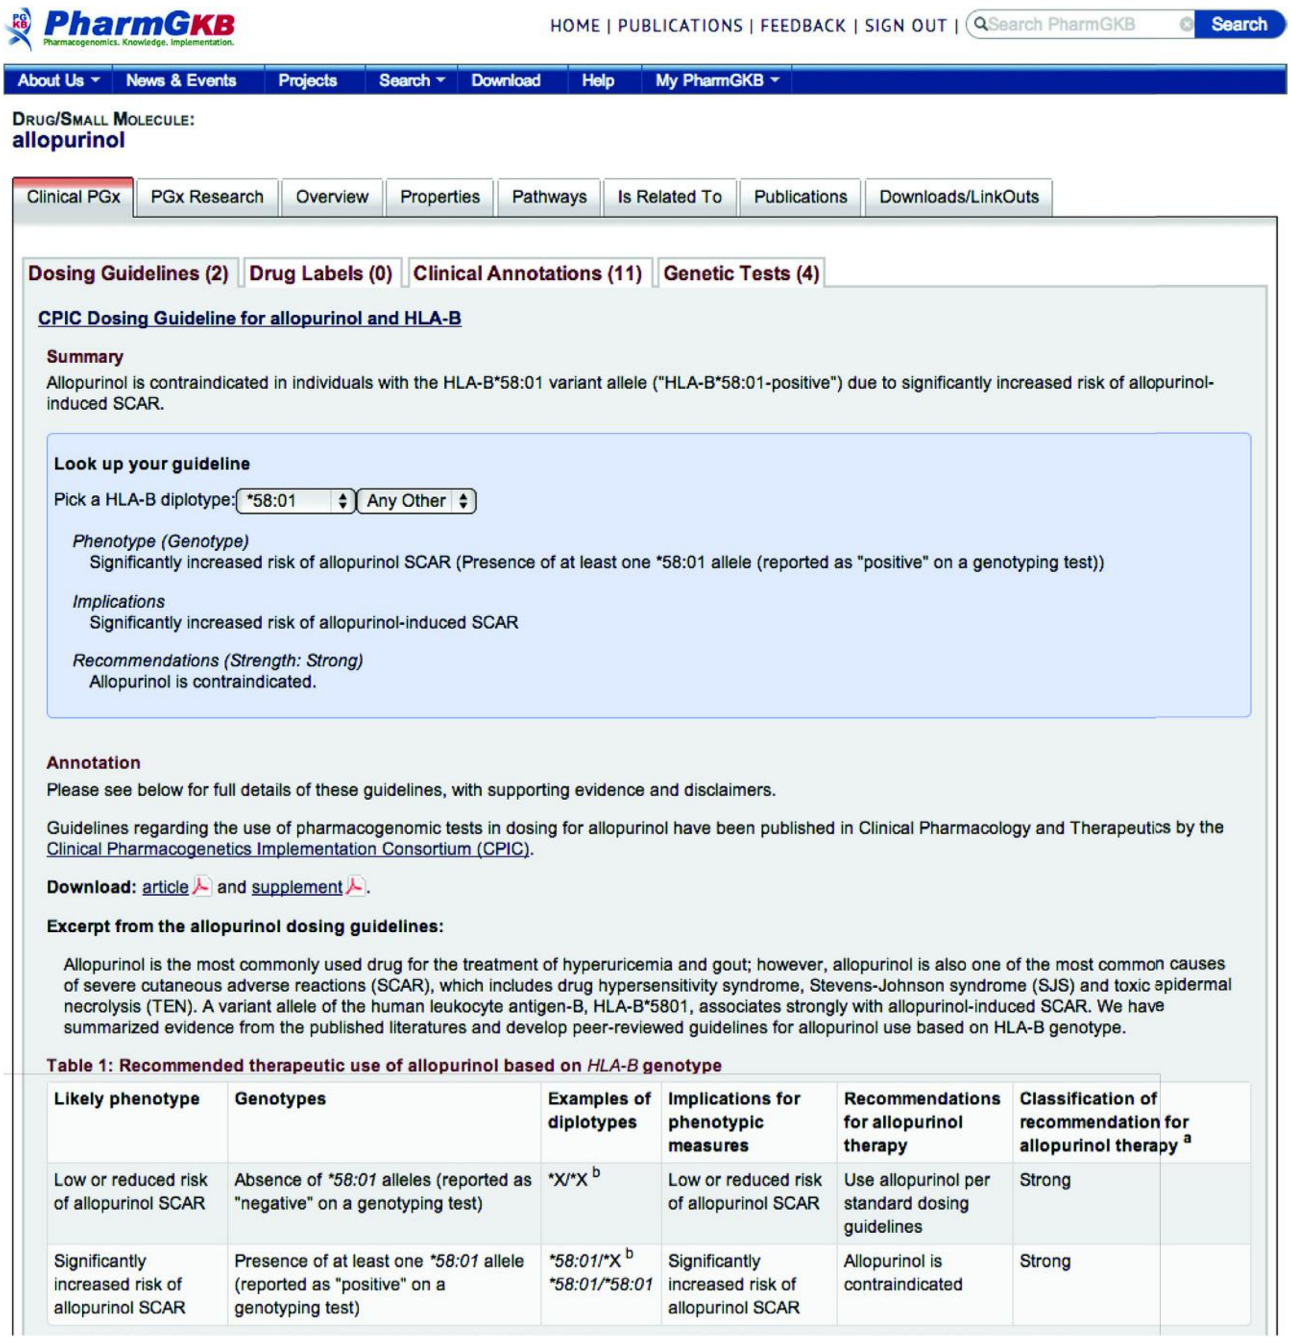
In addition to storing PGx knowledge and creating unique materials, PharmGKB also works closely with various consortia toward a common goal of clinical implementation. It is involved with two basic kinds of consortia: data-centric and knowledge-centric. Data-centric consortia consist of domestic and international groups conducting similar PGx studies. The goal is to gather their various study results into one or more analyses, increasing available ethnicities as well as study size and statistical power. Through these consortia, complicated genetic questions can be clarified and new and important pharmacogenomic variants may be discovered. The International Warfarin Pharmacogenetics Consortium (IWPC) is responsible for collating datasets on warfarin dosing from various pharmacogenomic research groups, and has so far released several papers on its findings [17,18] as well as a global dosing algorithm that utilizes the *VKORC1* and *CYP2C9* genotypes [19].

While dosing algorithms for warfarin had been previously proposed, they were usually based on data from small clinical populations and so had uncertain predictive accuracy. By bringing together data from over 4000 patients from 21 research groups around the world, the IWPC has been able to propose a reliable pharmacogenetic dosing algorithm that provides significantly more accurate dose estimates than a clinical dosing algorithm or a fixed-dose approach [19]. Because of its global reach, the IWPC analysis cohort consists of large numbers of black and Asian participants in addition to whites [19]. *VKORC1* polymorphisms are known to account for a smaller percentage of dose variability in blacks compared to whites or Asians, but prior to the formation of the IWPC, research on this ethnicity was difficult owing to low numbers of black participants in study cohorts [18]. The multiethnic nature of IWPC participants allowed the consortium to assess whether incorporating additional *VKORC1* variants into the dosing algorithm improved dose prediction in blacks or Asians [18], and perform a genome-wide association study to identify additional variants that may contribute to dose requirements in blacks [17].

Other consortia include the International Clopidogrel Pharmacogenomics Consortium (ICPC) and the International Consortium for Antihypertensives Pharmacogenomics Studies (ICAPS), which work to discover the genetic causes of variable response to clopidogrel and antihypertensives, respectively. PharmGKB acts as an independent broker of information in these consortia and therefore plays a crucial role in ensuring their success. It has no vested interest in the outcome and so can facilitate collaboration and analyses of these data. PharmGKB curators are experienced at harmonizing data across phenotypes, genotypes, and cultural differences, and they are therefore invaluable in keeping vast quantities of data organized. Current consortia are described on the PharmGKB website (www.pharmgkb.org/page/projects), and the knowledgebase is always open to new opportunities.

CPIC is a knowledge-centric consortium, consisting of members of NIH's Pharmacogenomics Research Network (www.pgrn.org), PharmGKB staff, and experts in both pharmacogenomics and medicine. While the goal of consortia such as IWPC, ICPC, and ICAPS is to amass datasets to answer a research objective, the aim of CPIC is to create detailed drug-dosing guidelines for clinicians who have access to pre-emptive genetic test results [15]. One of the major barriers to clinical implementation is a lack of freely available, peer-reviewed, updatable guidelines, and CPIC works to address this deficiency. Its guidelines target PGx associations that show substantial positive evidence, such as *HLA-B*58:01* and allopurinol [20] or *SLCO1B1* rs4149056 and simvastatin [21]. PharmGKB may suggest a CPIC guideline for an association based on a high-evidence-level clinical annotation.

Guidelines are written in a standardized format, consisting of background information on the gene, variant, and drug being discussed, information on genetic test options, and a discussion of the evidence linking genotype to phenotype. They culminate in specific therapeutic recommendations written in text form and presented as a table. Each guideline is written after an extensive literature review; PharmGKB staff and other CPIC members work in collaboration to conduct this review as well as to write the manuscript. Each therapeutic recommendation is given a strength rating, based on the quality and quantity of evidence as well as on whether the benefits of following the recommendations outweigh any possible undesirable effects. Most dosing recommendations receive a rating of "Strong." Ratings allow clinicians to make better-informed decisions about possible dosing modifications. More on these rating schemes can be found in the review by Relling and Klein [15] and in the supplementary material for any CPIC guideline.



DRUG/SMALL MOLECULE:
allopurinol

CPIC Dosing Guideline for allopurinol and HLA-B

Summary

Allopurinol is contraindicated in individuals with the HLA-B*58:01 variant allele ("HLA-B*58:01-positive") due to significantly increased risk of allopurinol-induced SCAR.

Look up your guideline

Pick a HLA-B diplotype: *58:01 | Any Other

Phenotype (Genotype)
Significantly increased risk of allopurinol SCAR (Presence of at least one *58:01 allele (reported as "positive" on a genotyping test))

Implications
Significantly increased risk of allopurinol-induced SCAR

Recommendations (Strength: Strong)
Allopurinol is contraindicated.

Annotation

Please see below for full details of these guidelines, with supporting evidence and disclaimers.

Guidelines regarding the use of pharmacogenomic tests in dosing for allopurinol have been published in Clinical Pharmacology and Therapeutics by the Clinical Pharmacogenetics Implementation Consortium (CPIC).

Download: article and supplement.

Excerpt from the allopurinol dosing guidelines:

Allopurinol is the most commonly used drug for the treatment of hyperuricemia and gout; however, allopurinol is also one of the most common causes of severe cutaneous adverse reactions (SCAR), which includes drug hypersensitivity syndrome, Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN). A variant allele of the human leukocyte antigen-B, HLA-B*5801, associates strongly with allopurinol-induced SCAR. We have summarized evidence from the published literatures and develop peer-reviewed guidelines for allopurinol use based on HLA-B genotype.

Table 1: Recommended therapeutic use of allopurinol based on *HLA-B* genotype

Likely phenotype	Genotypes	Examples of diplotypes	Implications for phenotypic measures	Recommendations for allopurinol therapy	Classification of recommendation for allopurinol therapy [a]
Low or reduced risk of allopurinol SCAR	Absence of **58:01* alleles (reported as "negative" on a genotyping test)	*X/*X [b]	Low or reduced risk of allopurinol SCAR	Use allopurinol per standard dosing guidelines	Strong
Significantly increased risk of allopurinol SCAR	Presence of at least one **58:01* allele (reported as "positive" on a genotyping test)	**58:01/*X* [b] **58:01/*58:01*	Significantly increased risk of allopurinol SCAR	Allopurinol is contraindicated	Strong

FIGURE 14.11 **CPIC guideline for *HLA-B**58:01 and allopurinol.** In addition to being published in *Clinical Pharmacology and Therapeutics*, CPIC guidelines are distributed through PharmGKB. Dosing guidelines can be found under the "Clinical PGx" and "Dosing Guidelines" tabs on the relevant gene and drug pages. Each page includes an excerpt from the guideline, the therapeutic dosing recommendations in table format, and links to the original article and supplement (the supplement includes information about the strength-rating scheme). PharmGKB also includes interactive dosing guidelines, which can be seen at the top of the page. Users can enter a genotype of interest and receive specific dosing guidelines for it taken from the dosing recommendations table.

CPIC guidelines are published in *Clinical Pharmacology and Therapeutics* and are open-source on PubMed Central. PharmGKB provides a list of published guidelines with links to PubMed at www.pharmgkb.org/page/cpicGeneDrugPairs; these guidelines are available for download from the website in JSON format. PharmGKB also presents the guidelines on its website in a simplified format, accessible through the relevant gene or drug pages. An example of the CPIC guideline for *HLA-B**58:01 and allopurinol is shown in Figure 14.11. An excerpt is included, as well as links to the original paper and the therapeutic dosing guideline table. CPIC guidelines on PharmGKB also include interactive dosing guidelines, where users can enter in their specific genotype of interest and receive dosing information sourced from the therapeutic dosing recommendations table. This functionality can be helpful for guidelines that have very large and extensive recommendation tables, or for users looking for quick information. Figure 14.11 shows the response to a request for information on *HLA-B**58:01 heterozygotes: for these patients, allopurinol is contraindicated because of an increased risk of severe cutaneous adverse reactions (SCARs).

In addition to distributing CPIC guidelines through its website, PharmGKB also sources dosing guidelines from other groups, such as The Royal Dutch Association for the Advancement of Pharmacy Pharmacogenetics Working Group (DWPG) [22]. A list of all dosing guidelines on PharmGKB can be found at www.pharmgkb.org/view/dosing-guidelines.do; guidelines from CPIC and DWPG are added as they are released. PharmGKB also sources drug labels that contain PGx information from the European Medicines Agency (EMA) [23] and from FDA-approved drug labels with PGx information from DailyMed [24,25]. If available, these can be found on their relevant gene and drug pages. PharmGKB presents an excerpt from the drug label as well as a downloadable copy of the label with the PGx information highlighted.

14.7 PROJECTS IN DEVELOPMENT

Data on PGx literature form the basis of all materials created on PharmGKB, and a current challenge for the knowledgebase is keeping pace with the large volume of literature being published. PharmGKB is integrating NLP technology to assist curators in the identification and extraction of PGx relationships from the literature, through a pipeline known as SemanticPGx, which automatically extracts novel gene–drug associations from PubMed. The pipeline begins with a download of all PubMed abstracts and, after several steps, including parsing and filtration, presents a collection of novel relationships ranked by the number of PubMed abstracts in which they appear. Novel relationships are defined as those between a gene and a drug that are not currently present on PharmGKB, where the gene in the relationship has a relationship with other PharmGKB drugs and the drug has a relationship with other PharmGKB genes. Curators can view this assortment of extracted relationships, assess them for relevancy and accuracy, and then consider annotation of the collected publications. This allows curators to maintain accuracy while permitting broader literature coverage and greater data input.

In addition to expanding the knowledgebase, PharmGKB is working on making the currently available data more easily accessible to both researchers and clinicians. This is achieved through two research projects: PGxplore and PGxpress. PGxplore is an interface that allows visualization of all PGx relationships in the knowledgebase. When entities are listed together in a variant annotation, clinical annotation, VIP summary, pathway, dosing guideline, or drug label, they are stored in the knowledgebase as a relationship. This creates a vast network of connections from multiple types of data. PGxplore allows users to visualize these links in a force-directed and entity-centered manner. Figure 14.12A shows a PGxplore image created for the drug tacrolimus, although complicated networks centered on drugs, genes, diseases, phenotypes, or variants can be created. Different-color lines represent the different sources from which the relationship is derived, showing the way in which tacrolimus is connected with a variety of genes and diseases through different PharmGKB sources.

As an example, Figure 14.12B zooms in on the connection between tacrolimus and *CYP3A5*. We have shown how these two entities appear together in a variant annotation (refer to Figure 14.3), a clinical annotation (refer to Figure 14.6), and a pathway (refer to Figure 14.10). They also appear together in a VIP as well as in a dosing guideline. In the image, the purple line shows that tacrolimus and *CYP3A5* are connected through a variant annotation; the blue line indicates a relationship through a clinical annotation; all other lines indicate relationships through other materials. A user can click on any connection to see supporting data.

This type of visualization provides an alternate way to learn about the interaction of genes, drugs, and phenotypes on PharmGKB, as compared to scrolling through tables. The networks can be complex, but the PGxplore environment provides many ways to simplify them (or make them more complex if that is desired), and a number of tools and options are available for exploring the data in depth. Indeed, data from any outside source can be uploaded to the platform as long as they are in an accepted format—PGxplore accepts data in many forms, including JSON, XGMML, OWL, and CSV, which allows for an expansion of research opportunities beyond PharmGKB. Overall, PGxplore provides an interactive and visually agreeable way to manipulate and comprehend data from PharmGKB or from outside sources, and it acts as a platform for the discovery of novel PGx associations and subsequent hypothesis generation.

While PGxplore focuses on visualizing domain knowledge and increasing accessibility to PharmGKB data, PGxpress streamlines PharmGKB knowledge for clinicians or researchers. PGxpress is a PGx mobile website that targets users who want high-impact PharmGKB data on smart phones or tablets. The main PharmGKB website is designed to be displayed on desktop screens, and pages often display extensive text and tables that are ideal for viewing large amounts of detailed content. However, navigating the website from a phone or tablet can be difficult for a researcher looking up a variant of clinical interest while away from his or her desk, or for a clinician with a patient wanting to check dosing guidelines. Gene and drug pages on PGxpress present clinically relevant information in condensed form, including dosing guidelines from CPIC and DWPG, drug labels, and annotation data. An example of the condensed

FIGURE 14.13 PGxpress page for clopidogrel. PGxpress presents clinically relevant information in a condensed format that is ideal for any screen size. From gene, drug, or variant pages, users can check for clinically relevant information, including dosing guidelines, drug labels, and annotation data.

page for clopidogrel, as viewed on an iPhone, is shown in Figure 14.13.

In addition, users can easily check for any necessary dosing modifications using drop-down boxes, and the overall format of PGxpress means this information is legible on any size screen. Links are also provided to the original drug, gene, or variant page on PharmGKB if more information is needed. Through PGxpress, PharmGKB provides direct access to key PGx information in a mobile format, expanding its data beyond the desktop and into the pockets of clinicians and researchers.

14.8 CONCLUSION

Through its collection of literature and data, PharmGKB has grown into the foremost knowledgebase of PGx information. Moreover, by providing this knowledge in multiple formats, it makes its information accessible and understandable to all types of users. Whereas researchers may choose to use variant annotation data for their studies, students may find VIPs and pathways ideal for learning about pharmacogenomics. Those interested in clinically relevant information have access to curated and evidence-rated clinical annotations. Through the efforts of CPIC and other consortia, PharmGKB can provide dosing guidelines for interested clinicians and help advance clinical implementation. Given the magnitude of knowledge available on its website, PharmGKB has worked carefully to ensure that all available information is highly curated, well organized, and easy to find. In addition to growing the knowledgebase, PharmGKB continues to work on new projects that increase the usability of its knowledge for both researchers and clinicians. Through these undertakings, PharmGKB endeavors to both broaden its user base and further pharmacogenomic knowledge.

Key Points about PharmGKB

What is the Pharmacogenomics Knowledgebase (PharmGKB)?
PharmGKB is a publicly available, online resource that provides information about the effect of human genetic variations on drug response. It also plays a large role in various consortia, which work globally to answer important pharmacogenomic questions and implement pharmacogenomics in the clinic.

What types of information can I find on PharmGKB?
PharmGKB extracts information from primary pharmacogenomic literature and presents it in the form of variant annotations; these data are also available for download for further research. The knowledgebase aggregates and integrates its data to create higher-level materials such as clinical annotations, very important pharmacogene (VIP) summaries, and pathways. Additionally, the website distributes information gathered from its work with various consortia, such as the drug-dosing guidelines developed as part of the Clinical Pharmacogenetics Implementation Consortium (CPIC). It also curates drug-dosing guidelines from other sources as well as U.S. and European drug labels that contain pharmacogenomic information.

What is a variant annotation?
A variant annotation is a summary of an association between a single variant and a drug phenotype as reported in a publication. A publication can have as many annotations as different associations found.

What is a clinical annotation?
A clinical annotation is an aggregation of variant annotations. It is a clinically oriented and genotype-based summary of a particular variant–drug phenotype association. Each clinical annotation is assigned a level of evidence based on the perceived strength of the association; these evidence levels provide a measure of the potential clinical relevance of a variant–drug phenotype association.

What are VIPs and pathways?
VIPs are overviews of important genes involved in drug response. Pathways are illustrations of the pharmacokinetics or pharmacodynamics of a pharmacogenomics-relevant drug, accompanied by informative text. Both VIPs and pathways are excellent starting places for a user to learn more about a pharmacogenomically important gene or drug.

What is PharmGKB's involvement in consortia?
PharmGKB plays a major role in various consortia that help drive clinical implementation forward. Data-centric consortia, such as the International Warfarin Pharmacogenetics Consortium (IWPC) and the International Clopidogrel Pharmacogenomics Consortium (ICPC), bring together domestic and international groups to address important genetic questions and discover new pharmacogenomic variants. PharmGKB works as an independent broker of information in these consortia and therefore plays an invaluable role in their success. PharmGKB is also involved in knowledge-centric consortia, such as the Clinical Pharmacogenetics Implementation Consortium (CPIC), which develops dosing guidelines for variant-drug associations with high levels of supporting evidence.

What is a CPIC dosing guideline?
CPIC dosing guidelines are recommendations for clinicians who have access to pre-emptive genetic test results; they are written by PharmGKB staff in collaboration with other CPIC members. Guidelines exist for variant–drug associations that show a preponderance of supporting evidence. In addition to background information, they provide specific therapeutic recommendations for a drug based on genotype accompanied by a strength rating. These guidelines are published, and PharmGKB provides interactive versions on its website.

GLOSSARY

Clinical annotation a genotype-based, evidence-rated summary of PharmGKB's literature evidence for a particular variant and drug phenotype association

Pathway an illustration of the pharmacokinetics or pharmacodynamics of a PGx-relevant drug, accompanied by informative text

Pharmacogene a gene involved in drug response

rsID (reference SNP identification) an identification number assigned by the National Center for Biotechnology Information (NCBI) SNP database (dbSNP) to a cluster of SNPs that map to the same location

Variant annotation a summary of an association between a single variant and a drug phenotype as reported in a publication

VIP (very important pharmacogene) summary a pharmacogenetic-based overview of an important gene involved in drug response

ACRONYMS AND ABBREVIATIONS

CPIC	Clinical Pharmacogenetics Implementation Consortium
dbSNP	National Center for Biotechnology Information (NCBI) SNP database
DWPG	The Royal Dutch Association for the Advancement of Pharmacy Pharmacogenetics Working Group
EMA	European Medicines Agency
FDA	U.S. Food and Drug Administration

15.1 OVERVIEW

Drug development is the process of bringing a new drug to the market and consists of multiple stages starting with the discovery of the lead compound, followed by preclinical research (conducted in microorganisms and animals), clinical trials (in humans), and regulatory approval to market the drug (Figure 15.1) [1]. The clinical development of a new drug is fraught with risk and uncertainty, with nearly 90% of human trials failing to achieve registration [2]. One strategy to improve the efficiency and effectiveness of drug development is to leverage pharmacogenomic information, particularly in the clinical trials stage (Figure 15.1). The rationale is that identification of patients with increased risk of adverse drug reactions or drug inefficacy enables early tailoring of treatment so that a more optimal benefit–risk ratio is achieved at an individual level. This contrasts with overall population level drug information obtained typically from current randomized controlled trials (RCTs).

The use of biomarkers to define population subgroups for treatment is the basis of stratified medicine, the implementation of which requires early biomarker development, appropriate sample collection in clinical trials, and development of the most relevant assays to achieve clinically interpretable results [3]. In contrast to standard clinical trials, a pharmacogenomic or stratified medicine clinical trial seeks to determine if the treatment effect of a drug varies between subjects with different genotypes and the cost–benefit ratio of genotype-guided treatment over standard care. This chapter provides an introduction to clinical trial methodology and explores the specific considerations required for pharmacogenomics and stratified medicine.

A clinical trial is a planned experiment on humans designed to evaluate the effectiveness of one or more forms of treatment. Clinical trials can be broadly classified into five phases (Table 15.1), which represent stages in the clinical development of a drug. Phases 0–III are done before a license is granted and phase IV is done after authorization. Phases 0–III can last up to 10 years, and in that time a majority of drugs (~90%) are withdrawn from development due to safety issues, poor pharmacokinetic/pharmacodynamic (PK/PD) profiles, and poor efficacy in patients with the target disease [2].

15.2 PHASE I STUDIES

Following Phase 0, further exploratory studies after the initial first-in-human study consist of trials using multiple ascending doses of the drug (investigational medicinal product, or IMP) in a small group of subjects to assess safety, determine a safe dosage range, and assess interaction with

TABLE 15.1 Clinical Trials

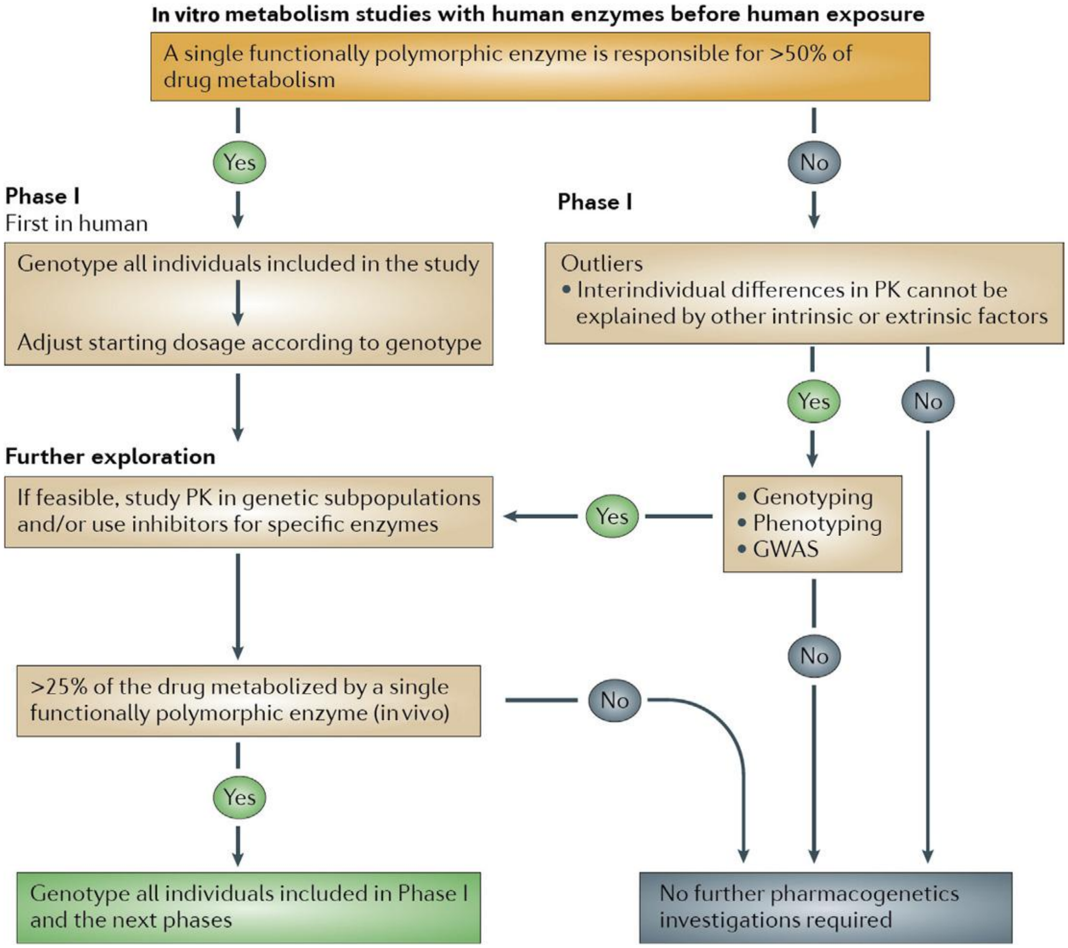
Phase	Objective
0	• First-in-human trials • Assessment of PK/PD, tolerability, and safety: single subtherapeutic doses of the study drug given to 10–15 subjects • Results with those of preclinical studies.
I	• Assessment of pharmacodynamics, pharmacokinetics, and toxicity. • Conducted in 50–200 healthy subjects or patients not expected to benefit from investigational product
II	• Initial clinical investigation of drug • Conducted in 100–400 subjects with target disease • Used to find best dose and investigate safety
III	• Full-scale evaluation of treatment • Generally major trials in (>1000–5000 subjects with target disease) • Aimed at conclusively demonstrating efficacy. • Typically studies on which registration of a new product based.
IV	• Post-marketing surveillance • Carried out after registration of a product • Can involve many thousands to millions of patients with target disease • Assess long-term safety of medicine (pharmacovigilance) and allow comparison with similar medicines. • Often for marketing purposes as well for broader experience with use of new product

food, gender, and other medicines. Furthermore, additional information on PK parameters of absorption, distribution, metabolism, elimination, and bioavailability are obtained using radiolabeled drug molecules; the effect on cardiac repolarization is assessed by reviewing changes in the QT interval in the electrocardiogram. Subjects who volunteer for phase I trials get no therapeutic benefit from the IMP, so appropriate and rigorous risk assessments are required, before the trial, to minimize the risk of harming the subjects. The overall safety of Phase I trials is good, with an incidence of 0.02% of serious adverse events related to the investigational drug [4]; however, there is paucity of safety data on nonchemical investigational drugs such as proteins, cytokines, and monoclonal antibodies.

There are several guidelines on calculating a safe starting dose on the IMP in Phase I trials [5,6]. The FDA [6] uses a stepwise model:

1. Convert the no-observed-adverse-effect dose level (NOAEL) from the toxicology studies to a human equivalent dose (HED) on the basis of body surface area.
2. Select a HED from the most appropriate species.
3. Apply a safety factor (10-fold) to give a maximum recommended starting dose (MRSD).
4. Adjust the MRSD on the basis of the predicted pharmacological action of the IMP.

An alternative or complementary method is to calculate the safe starting dose based on the minimal anticipated biological effect level (MABEL)[5] see also the Joint



In vitro metabolism studies with human enzymes before human exposure
A single functionally polymorphic enzyme is responsible for >50% of drug metabolism
Yes
No
Phase I
First in human
Genotype all individuals included in the study
Adjust starting dosage according to genotype
Phase I
Outliers
• Interindividual differences in PK cannot be explained by other intrinsic or extrinsic factors
Yes
No
Further exploration
If feasible, study PK in genetic subpopulations and/or use inhibitors for specific enzymes
Yes
• Genotyping
• Phenotyping
• GWAS

For polymorphic enzyme systems for which well-validated *in silico* physiologically based pharmacokinetic (PK) models have been developed, pharmacogenetic differences in humans may be predicted and used as a guide for clinical study design with respect to pharmacogenetics investigation. GWAS—genome-wide association study. *Source: Reprinted with permission from Maliepaard et al.* [11].

ABPI/BIA Taskforce Report, 2006. This approach uses all relevant information, including novelty, potency, mechanism of action, degree of species specificity, dose-response data from human and animal cells *in vitro*, dose- and concentration-response data from animals *in vivo*, pharmacokinetic and pharmacodynamic modeling, calculated target occupancy versus concentration, and target or target cell concentration in humans *in vivo*. In a dose-rising trial, the dose is usually doubled at each increment, a practice justified by a log-linear dose-response curve.

Studying healthy volunteers instead of patients may reduce variations caused by disease, advanced age, co-medications, and other factors. A limitation is that usually only surrogate parameters of efficacy or side effects can be measured. Nevertheless, these studies have played a major role in improving our understanding of pharmacogenetic polymorphisms such as those in CYP2D6, CYP2C19, thiopurine methyltransferase, and N-acetyltransferase type 2. Phase I studies in twins helped establish early heritability of drug pharmaockinetics [7].

Pharmacogenetic variations may be predicted from *in vitro* studies prior to the first application of the drug in humans. Both the FDA and the European Medicines Agency (EMA) have provided some guidance on integrating pharmacogenetics in early-phase clinical studies (Figure 15.2). The rationale for using pharmacogenetics in Phase I trials is primarily to facilitate successful drug development. For example, genetic variants can explain lack of efficacy or ADRs and prevent early failure of a new IMP. It may be much less expensive to include some pharmacogenetic analyses directly in phase I, rather than perform separate human pharmacogenetic studies later, because having the clinical pharmacogenetic knowledge before starting phase II allows for informed decisions about whether to stratify, exclude, or adjust according to pharmacogenetic diagnostics in phase II trials. Estimation of the relative impact of pharmacogenetic variation versus drug–drug interaction effects, effects of age, effects of body weight, and so forth, allows for the development of the correct priorities and exclusion criteria in phase II studies [8,9].

FDA guidance [10] emphasizes the importance of considering data from preclinical assessment in determining the best approach in Phase I studies. For example, after *in vitro* studies, clinical pharmacology studies may be used to identify any association of the IMP's PK/PD with genetic variants in metabolizing enzymes, drug transporters, and drug targets. If it is determined during preclinical testing that the IMP is metabolized by a well-established polymorphic gene (for example, cytochrome P450), the guidance recommends that the contribution of genetic variants to PK variability, and subsequently to dose or dosing regimen selection in human studies, should be evaluated.

The EMA has also developed detailed guidelines on assessing pharmacokinetic pharmacogenetics in Phase I studies of novel drugs [11]. When the *in vitro* data indicate that >50% of the drug is cleared by a single functionally polymorphic enzyme, it is recommended that relevant gene be genotyped in the first-in-human (Phase 0) study population to avoid safety issues related to genetically determined differences in active substance exposure. Subjects with a poor metabolizer genotype (which can result in higher levels of the active drug or its metabolites) are allowed to participate in the first-in-human study only at doses lower than those expected to be safe in individuals who have an extensive metabolizer phenotype. Further exploration studies require investigation of the relative contribution of an important polymorphic enzyme on the *in vivo* PK properties of a drug or active metabolite, usually in a conventional PK study within genetically defined subpopulations whenever feasible [11]. When this is impractical, and when there is ample supporting scientific literature or validated data available, the effect of a genotype may be confidently mirrored by treatment with an inhibitor of the respective metabolizing enzyme; the effect of the polymorphism can then be estimated from the results. In such cases, it is important to consider off-target effects of the respective inhibitors. If a marked effect of a polymorphism is confirmed *in vivo* (arbitrarily defined in the EMA guideline as when >25% of the parent drug is cleared by the polymorphic enzyme *in vivo*), genotyping the indicated genes is recommended in as many of the Phase I studies and the next phases as possible. This is to maximize the amount of supporting data for recommendations utilized in studies of genetically defined subpopulations [11,12].

The FDA considers any level drug metabolism by a single polymorphic enzyme to be important, because it is relevant to drugs with steep exposure–response relationships. (This is in contrast to the EMA, which uses a threshold of >50% of the drug to be cleared by the enzyme in *in vitro* studies). When *in vitro* studies suggest that a drug is metabolized extensively by a polymorphic enzyme, FDA guidance recommends that pharmacogenetic analyses be conducted in single- and/or multiple-dose PK studies to evaluate the impact of common genetic variants on *in vivo* drug concentrations (and relevant PD measurements if available). Consideration of known differences in the prevalence of ADME-related gene variants among racial or ethnically distinct groups should be incorporated into the planning for such analyses. Selected genetic variants (for example, SNPs in genes encoding metabolizing enzymes) that occur with acceptable prevalence in the population should be studied. A dedicated clinical pharmacology study with targeted, genotype-based enrollment may be desirable in certain situations and should allow a meaningful retrospective analysis [12].

If a drug is converted into an active metabolite through a polymorphic metabolic pathway, rather than a candidate gene study, other strategies that include the screening of subjects in early-phase clinical trials using high-throughput methodologies (for example, ADME "gene chips") may generate valuable information on the sources of PK and/or PD variability.

15.3 PHASE II STUDIES

Phase II studies are dose-finding investigations performed to aid the design of subsequent Phase III studies, including the decision of whether or not genotype-based dosing should be applied. **The standard phase II design is** a single-arm study that tests the null hypothesis of insufficient efficacy versus sufficient activity meriting further investigation. A type I error defines the chance that an ineffective agent will be studied further; a type II, error the chance that an effective agent will not be studied further, which is usually regarded as the more serious error in phase II testing. Phase II clinical trials are able to detect only a large treatment improvement (e.g. greater than 10%) because the sample size is small. An important characteristic of some phase II trial designs is the use of early stopping rules. If there is sufficient evidence that one of the treatments under study has a positive treatment effect, patient accrual is terminated and the treatment is declared promising. Also, if a treatment is sufficiently shown not to have a desirable effect, patient accrual is terminated and the treatment is declared not promising.

A **randomized phase II selection design** allows multiple single-arm studies to be conducted in the same timeframe and with the same entry criteria [13]. Typically, this randomizes between two or more experimental arms without a control arm [3,4,8]. Usually, there will be a test for the activity of each arm, using standard criteria for single-arm studies, and a rule for selecting the "best" of the active arms for further testing. Often, the rule for a selection design study is to select as "best" the arm with the best efficacy level, no matter what the magnitude of the difference. There is generally not adequate power for formal tests comparing arms. A weakness of this design is the reduced likelihood of being able to select the best arm if there are an increasing number of arms or if there is a small difference in activity among them [14]. The advantages of a randomized study over separate studies include decreasing the effects of patient selection bias, population drift, and stage migration, and the ability to ensure that uniform evaluation criteria are used.

Whereas a randomized selection design may have advantages when screening multiple treatments, a **randomized controlled phase II study** may be useful when fewer comparisons are required. This design typically compares an experimental arm to a control arm (with or without a placebo). In settings where an effective therapy exists, the control arm might consist of effective standard therapy plus placebo. The added expense of a placebo and the administrative burden need to be weighed against the potential for bias. The effectiveness of the placebo in blinding treatment should also be considered because many agents have significant side effects.

Comparison to a control arm is most useful when there is little prior information on expected efficacy rates in a population; it can also be useful for end points, which can be heavily influenced by patient selection, such as time to progression end point (TTP) and progression-free survival in cancer studies [15]; and when it is expected that improvements in supportive care or other clinical factors will change the expected outcome in the population being studied. The efficacy end point can be a standard measure of disease status such as objective response or TTP, allowing the study to be completed with fewer patients than required in a phase III study of survival. Because the primary end point is not survival, a crossover to the drug from the placebo arm when the end point is reached can also be considered; it is advantageous because it attracts patient accrual. However, its weakness is that it can dilute determination of a survival benefit.

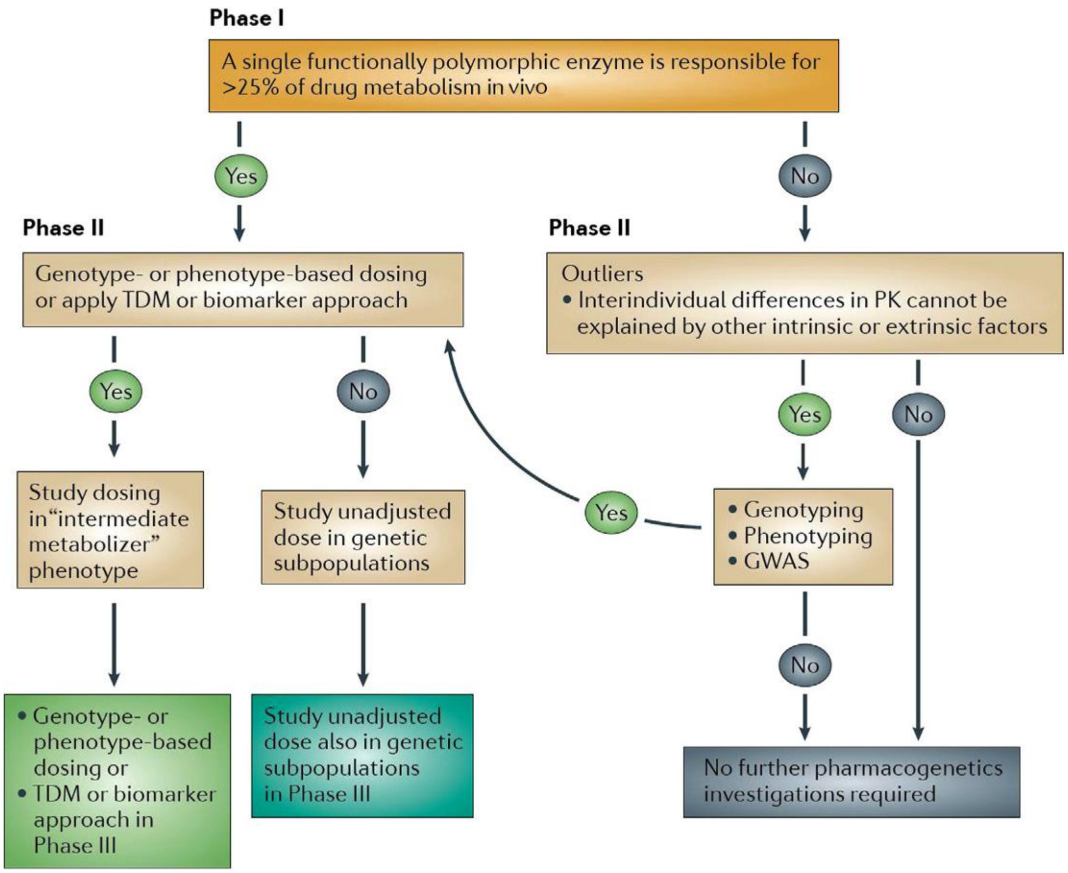
For evaluating TTP in a study with crossover at progression, there is usually a serious risk of bias, especially when the control arm includes no active agents. However, in many phase II studies the magnitude of the potential bias should be small relative to the effect that can be detected. Type I and II error rates vary, but as in other phase II designs, the type I error can generally be larger than in phase III—Korn et al. [15] suggest considering one-sided type I error rates as large as 20%. The magnitude of the difference between the null and alternative hypotheses may also be larger than appropriate for a phase III study. A potential weakness of a randomized phase II control design is the need for a second larger study. A decision as to whether a single-arm phase II study will be adequate to make a decision to go forward to a phase III study, or whether a randomized comparison with a progression end point will be required, should be made prospectively.

A **randomized discontinuation design** is an example of an enrichment strategy [16] in which patients are randomized between continuing the drug or going on a placebo if free of progression at some defined time point. Patients are usually crossed over from placebo to treatment at progression or at a specified progression-free interval. Those who are responding continue on therapy until progression. The design is complex, with three registration points: initial registration, at the defined time of randomization during stable disease, and crossover at progression. It is most attractive in settings where it is thought that only a subset of the population will benefit from the treatment, which might be the case for some targeted therapies. It has been shown that while theoretically effective in these settings, their effectiveness depends on the extent to which the initial run-in can select out the subgroup that is clearly benefiting on the basis of disease stabilization versus rapid progression [17]. Potential weaknesses of this study design include the possibility of a carry-over effect from the run-in that could dilute differences between the randomized arms. Desired patient numbers also need to be considered carefully because these studies tend to be much larger than other phase II studies.

The EMA recommends that potential clinically relevant pharmacogenetic influences on drug PK properties from Phase I studies be considered in the design of Phase II studies, either by investigating genotype-based or phenotype-based dosing or by exploring therapeutic drug monitoring (TDM) or biomarker-guided dosing (Figure 15.3) [11,12]. When Phase II data indicate that the difference in exposure observed between genetically defined subpopulations is likely to be of clinical importance, individuals with an intermediate metabolizer phenotype should be investigated in a further PK study. If the sponsor decides that dose adjustment is not needed based on genotype, TDM, or biomarker data, the exposure level obtained with an unadjusted dose in the genotypically defined subpopulation should also be used in Phase II studies [11,12].

FDA guidance recognizes that important PK variability of an active parent drug (or metabolites), if observed in Phase I trials, should shape the design of subsequent clinical studies (for example, dose–response studies in genetically defined subpopulations). For cases in which genotypes are found to be relevant in predicting exposure and drug effect, this knowledge should be used in the design of subsequent clinical trials. For example, genotypes can be used to select patients for trials (e.g., enrichment with responders or exclusion of patients likely to experience toxicity); stratify groups within trials; and adjust doses for trials. This strategy may increase average effect, decrease toxicity, and improve the chances for overall study success.

Another important aspect of the design of clinical pharmacology studies is the pharmacogenetic evaluation of



Phase I

No
• Genotype- or phenotype-based dosing or
• TDM or biomarker approach in Phase III
Study unadjusted dose also in genetic subpopulations in Phase III
No further pharmacogenetics investigations required

FIGURE 15.3 **EMA decision tree for Phase I and Phase II studies.** *Source: Reprinted with permission from Maliepaard et al.* [11].

dose–response relationships. If the genotype is shown to be associated with systemic exposure–response (activity and/or safety) in early PK or PD studies, subsequent dose–response studies with methodological features including, but not limited to, genotype-based dose stratification should be considered.

Ideally, pharmacogenetic variants relevant to drug metabolism and transport are already included in late Phase II trials to enable PGDx-based dose adjustments in subsequent Phase III trials. However, if the population frequency of a typical pharmacogenetic polymorphism is >50%, then it is clear that pharmacogenetic questions can only be solved in larger Phase III trials.

15.4 PHASE III STUDIES

Phase III trials are also called comparator trials or controlled trials, as they involve direct comparison between two or more treatments (Figure 15.4). In this phase, data are gathered from large numbers of patients (hundreds to many thousands) to find out whether the new treatment is more effective and possibly has fewer side effects than the current standard treatment. These clinical trials take many years to complete. Although phase III clinical trials focus on patients with a specific disease, they typically include patients of different ages, ethnicities, and genders so that the results will be applicable to a large number of people.

A major problem is the possibility of bias distorting the results of the study, and studies are rigorously planned to minimize it. Usually a treatment or a sequence of treatments is assigned to each group and subjects are followed up prospectively and simultaneously. The former case is referred to as a parallel group design; the latter, as a cross-over design. Three types of bias commonly observed:

- Selection bias is defined as a nonrandom imbalance among treatment groups of the distribution of factors capable of influencing the end points—that is, of subexperimental factors (including prognostic factors). This is mitigated using randomization (see Box 15.1).
- Assessment bias is defined as a nonrandom imbalance among treatment groups in the way subjects are followed and assessed during the study. It can be mitigated using suitable blinding procedures (see Box 15.2).

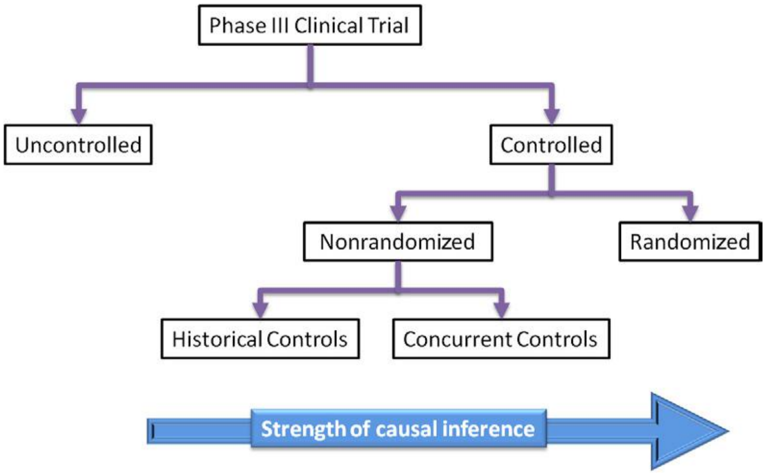

FIGURE 15.4 Phase III clinical trials.

BOX 15.1 Randomization

Randomization is a process that assigns research patients by chance, rather than by choice, to either the treatment group or the control group. This implies that each individual assignment cannot be predicted based on previous assignments. Put simply, at each assignment each subject has the same probability of being assigned to each treatment: this probability is 50% in a study with two treatments, 33.3% in a study with three treatments, and 25% in a study with four treatments. In addition to minimizing selection bias, by introducing a random element into the assignment of selected subjects, randomization allows the application of the statistical significance test.

In *simple randomization*, each patient has the same probability of receiving each of the study treatments (or sequence of treatments). This is usually achieved by tossing a coin or generating random numbers.

Permuted block randomization is a form of restricted randomization in which blocks of k patients are created such that balance is enforced within each block. One of the blocks is then selected at random and the k patients are assigned accordingly. This promotes group balance at the end of the trial, as well as periodic balance in the sense that sequential patients are distributed equally between groups. This type of randomization can be susceptible to selection bias.

In *stratified randomization*, if a covariate (e.g., age, gender, race, or center) is known to be the cause of heterogeneity among patients, patients are stratified into several homogeneous strata with respect to it. Randomization is then performed within each stratum (usually blocked). Stratified randomization guarantees treatment balance within risk factors. An extreme case of stratification is matching (common in case-control studies).

BOX 15.2 Blinding

Blinding/masking is used to prevent research outcomes from being influenced by either the placebo effect or observer bias. It does so by blocking the identity of the treatments. Blinding/masking embraces a multiplicity of situations in which the researcher systematically favors patients belonging to one treatment group over another when carrying out procedures linked (directly or indirectly) to the assessment of response to treatment. Commonly, a study is defined as double-blind when neither the research staff nor the patients know which study treatment is administered to an individual patient. When only the patients are unaware of the study treatment, the study is defined as single-blind. A study in which there is no blinding is defined as open-label. Triple-blind studies are those in which none of the patients, investigators, or sponsors know the treatment.

Phase III Study Designs

- Randomized Control Trials (parallel design)
- Uncontrolled Trials (single-treatment)
- Historical Controls
- Nonrandomized
- Concurrent Trials
- Crossover Designs
- Factorial Designs
- Group Sequential Design

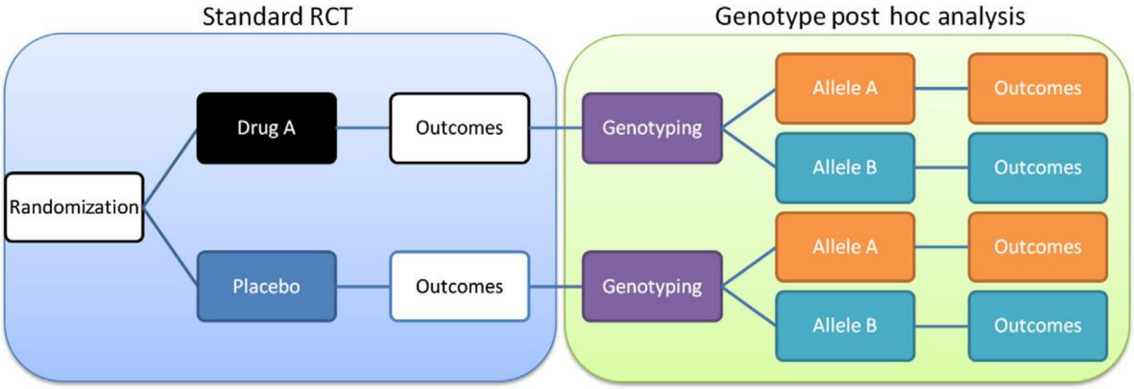

FIGURE 15.5 **Randomized trial with post hoc analysis.**

- Analysis bias is defined as a distortion in favor of one of the treatments, intervening during the data analysis, and is minimized using an *a priori* definition of the statistical methods and populations.

15.4.1 Randomized Controlled Trials

Randomized controlled trials (RCTs) are the gold standard for testing new medicines; they have an important role in determining the efficacy and safety of interventions. An RCT is characterized by shared principles: randomization of subjects into treatment and control groups; blinding of all participants as to which group subjects are in; the need for follow-up; and the handling of dropouts and withdrawals (see Boxes 15.1 and 15.2). Within an RCT, a subject will be randomly allocated to a group that receives one of the treatment options or a placebo. Typically, each group contains the same distribution of relevant demographics, such as age, sex, and ethnicity. RCTs are typically time-consuming, and large sample sizes are often needed to ensure sufficient statistical power. Still, they at best demonstrate the small relative benefit of a 15–20% relative reduction in a composite clinical end point.

RCTs may be classified into two subtypes depending on what they seek to prove [18,19]. Explanatory RCTs (ERCTs) evaluate the efficacy of a pharmaceutical agent under highly controlled conditions that do not necessarily reflect real life. Pragmatic RCTs (PRCTs) assess the effectiveness of a treatment in everyday situations, meaning that a less than strict adherence to the treatment regimen is not a reason for subject exclusion. ERCTs can produce more precise assessments of a pharmaceutical agent, although the trial design often deviates significantly from daily routine and the results are suited to the “average patient,” who does not exist. Also, they are not ideal for tailoring treatment to an individual, and without prior consideration of the underlying genetics, patients in a particular trial group might receive a drug that is ineffective for their genotype or, worse, dangerous [18]. PRCTs, on the other hand, generate weaker evidence but better reflect the circumstances of patients as they go about their daily lives.

Pharmacogenomic clinical trials can be designed (or analyzed post hoc) with the intention to study whether a subgroup of patients, defined by certain genetic characteristics, responds differently to the treatment (Figure 15.5). Alternatively, a trial can be intended to verify whether genotype-guided treatment is beneficial over standard care. For example, gefitinib, a lung cancer drug, inhibits epidermal growth factor receptor (EGFR) signaling in target cells, providing patients with a significantly longer period without disease progression and fewer side effects than with conventional chemotherapy [20]. Only patients with a specific mutation in the gene that encodes EGFR receive any benefit from gefitinib; however, initial clinical trial results were negative because none of the subjects had been selected based on EGFR activity. Positive clinical results were seen only after these subgroups were identified [21,22].

Using data from a completed trial in which DNA was already gathered at baseline and stored (as is more and more the standard practice in Phase III trials), a PGx subgroup analysis is relatively simple, fast, and inexpensive. If the outcome event is independent of the gene under study, which means that the gene is not a prognostic factor for the outcome, it is valid for the trial to be what is known as an exposure-only. Then only data from treated patients are taken into account, which is justified because the risk for the outcome is identical for all untreated patients regardless of their genotype. The Exposure-only design has been applied in the study of cardiovascular outcomes in subjects with acute coronary syndromes treated with clopidogrel, with the assumption that there is no direct association between CYP alleles and cardiovascular outcomes [23].

The major disadvantages of a subgroup analysis include the following: type I error may increase when analyzing many subgroups; confounding bias can be introduced if the subgrouping variable is associated with another variable that also modifies the treatment effect; and genetic differences in allele frequencies between subgroups (population stratification) may lead to misleading conclusions if the distribution of these populations is unequal between the strata. In the case of pharmacogenetic subgroups, the chance of introducing bias is small since inheritance of a specific genotype is in general independent of inheritance of other traits. However, bias may be caused by selective consenting for genotyping by participants. At the start of the study, this phenomenon is not likely to introduce bias because consenting is not related to study outcome. If, however, DNA or other biomaterial is collected (which can be reused for post hoc genotyping), the availability of the material might be selective owing to more frequent use from exceptional patients. If there is no DNA collected at baseline and it needs to be collected post hoc, a bias might be introduced by a selective loss of patients or by selective consenting by participants, because the study's outcomes can influence the decision to consent.

With an **enrichment design**, all potentially eligible patients are first tested for the genotype or biomarker and only biomarker positives are randomly assigned to the experimental or control treatment (Figure 15.6). Other patients are in principle excluded from further investigation in the study. This is similar to the post-hoc study design, except the subgroup analysis is planned a priori. If the prevalence of the selected genetic variants is unequal, it is possible to selectively include participants to create balanced numbers in the genotype strata [24].

The pivotal trial for trastuzumab is a well-known example of an enrichment design [25] in which patients with HER2-positive breast adenocarcinoma (human epidermal growth factor receptor 2, or HER2) were enrolled and randomly allocated to chemotherapy with or without trastuzumab. This study provided strong evidence that trastuzumab combined with chemotherapy improves outcomes among women with HER2-positive breast cancer.

With genotype information available before randomization, it is also possible to select patients with genotypes between which the largest difference in treatment effect is expected, instead of including all genotypes. In a "classical" enrichment design, only patients expected to show the greatest benefit from the intervention are enrolled. Using pharmacogenomics information in the selection is also possible by excluding genotypes assumed to be associated with an increased risk for side effects or nonresponse. This strategy reduces sample size and can increase subject safety; thus, it may eliminate the need for other safety measures—for example, close monitoring of drug plasma concentrations during the trial [26]. Its main advantage is that sample size is determined taking the planned subgroup analysis into account, which decreases the risk of insufficient statistical power at the end.

Bias introduced by selective consenting is avoided by genotyping at the beginning of the study as well. Moreover, the possibility of randomization by genotype, creating balanced numbers of genotypes per treatment arm, further increases the chances of a significant result and minimizes the possibility of confounding introduced by unequal genotype distribution between subgroups [27]. Selective inclusion of particular genotypes to create similar numbers of subjects in the genotype strata may prolong recruitment time if a prespecified number of patients carrying a rare allele are to be included. If time is a limiting factor, it might be a better option to settle for fewer patients with the rare genetic variant—a genotype ratio of 2:1 instead of 1:1, for example—which results in only minimal loss of power. Helpful in this consideration is the number needed to genotype in order to find an eligible patient; this number is calculated by dividing one by the prevalence of the genotype(s) under study [28].

When the existing evidence is not strong enough to exclude a subgroup of patients based on genotype, an **adaptive trial design** provides an alternative. In this design, the accumulation of data is used to modify aspects of the study because it continues without undermining the trial's validity and integrity.

Adaptive clinical trial designs are likely to be a vital component of drug development for multiple-target therapeutics [29]. Such designs, exemplified by I-SPY2 ("investigation of serial studies to predict your therapeutic response with imaging and molecular analysis 2") and BATTLE ("biomarker-integrated approaches of targeted therapy for lung cancer elimination"), allow researchers to review data during the clinical trial and adapt patient recruitment accordingly. Depending on early response assessment, such trials might allow researchers to test patient cohorts selected for multiple potential biomarkers for different therapeutic approaches and prioritize patients for distinct arms of the trial.

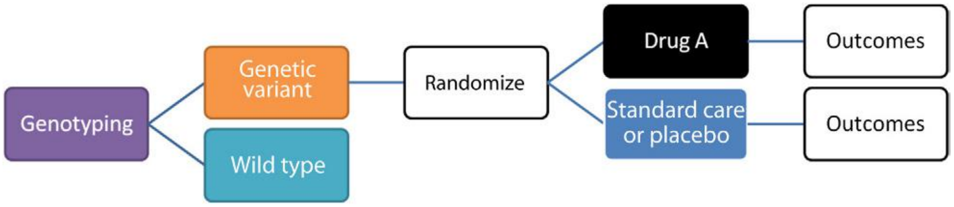

FIGURE 15.6 **Enrichment design.**

Designs such as the adaptive clinical trial require robust and advanced statistical techniques and may heighten the risk of false-positive conclusions. Particular care must be given to determining whether a putative predictive biomarker may also have prognostic relevance, where patient cohorts may have a superior outcome determined by the biomarker used to select them rather than the systemic therapy itself. Because of the requirement for interim analyses and clinician unblinding, traditional double-blind standards may be affected [29].

It was only in 2007 that the EMA published a paper outlining the appropriate conduct for adaptive-trials, and only in February 2010 that the FDA followed suit with its draft guidance to industry [29]. By changing the patient population to one that is more likely to benefit from a treatment, adaptive trials can inflate the risk of reaching a false-positive conclusion. They also run the risk that the interim data required to take that step to modify the trial might compromise it's double-blind safeguards, influence patient and investigator behavior, and color the results even further. For these reasons, the FDA and the EMA advise against using an adaptive trial when a standard trial will do, and urge extra caution in designing the late-stage clinical trials that are crucial to determining drug approvals.

In the **parallel controlled pharmacogenetic diagnostic study** (Figure 15.7), randomization is performed either in genotype-guided treatment or in standard care [8,27]. Genotype-guided treatment can include an alternative treatment (or exclusion) for subjects with predetermined genotypes. Or an algorithm that includes a subjects' genotype (and possibly other parameters such as age and weight) can be used to determine the initial or maintenance dose in this treatment arm. Analysis of this RCT is similar to that in a "regular" RCT, in which two interventions are compared. The advantage of parallel controlled studies is that their results deal with some of the main barriers to clinical uptake: skepticism toward clinical evidence and a perception that alternative ways of handling the risks of ADRs suffice [8,27]. Also, methodological or logistical challenges in implementing genotyping in daily practice may arise during the study that were not considered outside the trial setting.

One of the first RCTs to use this study design, randomly assigned HIV-infected patients to either prospective HLA-B*57:01 screening or standard-care use of abacavir [30]. The results, combined with results from previous observational studies, were reason enough to change abacavir's FDA drug label. Randomization to either standard care or pharmacogenomics-based treatment, enables a direct estimate of the benefit that genotyping provides to the prevention of ADRs or nonresponse. This estimate is necessary to assess the cost-savings of genotyping [31]. At the same time, a "break even point" of the benefit can be calculated, illustrating the number of patients needed to genotype, and treat accordingly, for the testing to be (cost-) effective.

In the "randomize-all" or "all-comers" study design, all patients meeting trial eligibility criteria, irrespective of their biomarker or genotype status, are randomly allocated to either experimental or control treatment, after which associations between biomarker status and treatment response are evaluated. This study design has the same patient flow elements as RCTs for evaluating treatment options. Alternatively, a biomarker can be evaluated retrospectively, using data and stored biospecimens collected from previously completed RCTs. In such scenarios, trials are commonly labeled "biomarker analysis within an existing RCT" or "prospective/retrospective" [32,33]. Type of randomization is another source of variability in labeling of randomize-all trials. In cases where a simple 1:1 randomization procedure is applied to all patients, trials are labeled "simple randomization." However, in cases where the biomarker under evaluation is binary or categorical with few categories, randomization can be done separately for each biomarker category through stratified randomization. Labels such as "biomarker-stratified," "stratified randomized," "nontargeted RCT (stratified by marker)," "stratified analysis," "stratification," and "separate randomization," all refer to this randomization type [34]. A special case of stratified randomization is randomization performed by means of a Bayesian response-adaptive procedure, rather than a standard equal-randomization procedure; this is known as "Bayesian adaptive randomization design" or "outcome based adaptive randomization"[35].

Another study design is the biomarker strategy in which biomarker status is assessed in all patients enrolled in the trial, who are then randomly allocated to either the biomarker strategy arm or to the standard treatment arm. There

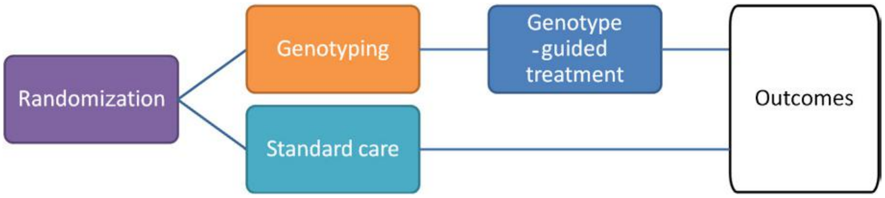

FIGURE 15.7 **Parallel controlled pharmacogenetic diagnostic study**.

is also modified marker-based strategy design, in which a second randomization between experimental and control therapy replaces the control arm [34].

A modification of the pharmacogenomic cohort study frequently preferred is the **nested case-control study**, also known as a **case-cohort study**. It is not necessary to analyze all subjects of the RCT; typically, selection is of all available participants of the study who had the outcome of interest (cases) and randomly selected participants who did not have the outcome of interest (controls). Typically, one control per case is chosen, but power can be increased by including up to four controls per case. Although the term "nested case-control" refers to a retrospective design, this type of study is indeed prospective in nature. It differs from retrospective case-control studies because it is only a random selection from a prospective cohort and therefore many serious types of bias known to arise in case-control studies are absent. A recent example of this study type involved statin-induced myopathy [36].

One of the drawbacks of RCTs is that they are conducted in artificial environments where significant attempts are made to control all factors that can influence outcome. Thus, an artificial increase in the standard of care may result in dilution of the effect of a biomarker in decision making. In addition, it has been suggested that the simple fact of participating in a RCT may have a positive effect on outcome, which may further complicate the generalization of the findings from a RCT to the general population [37].

15.5 PHASE IV TRIALS

An important source of data for pharmacovigilance is individual case reports (or case series) related to ADRs. Fatal outcomes reported in carriers of certain inherited variants may stimulate further research and attract increased funding for pharmacogenomic studies. Case reports do not provide generalizable results, which is a major limitation.

15.6 RETROSPECTIVE ANALYSIS OF CLINICAL DATASETS

Retrospective subgroup analyses have proven valuable in defining distinct patient subgroups that benefit preferentially from targeted therapeutic approaches. Examples include EGFR monoclonal antibody therapy benefit and KRAS wild-type status [38], HER2 status and paclitaxel benefit [39], and EGFR mutation status and gefitinib survival benefit [40]. Retrospective analyses have proven useful to several functional genomics RNA interference strategies in defining the relevance of a putative biomarker to treatment response in defined breast cancer subtypes [41–43].

Retrospective molecular analyses of clinical trial tissue datasets can prove fruitful in determining the predictive relevance of previously defined molecular aberrations, such as the importance of chromosome 17 centromeric enumeration probe duplication and anthracycline benefit in the adjuvant therapy of primary breast cancer [44]. The case–control design is the most frequently applied observational retrospective study in PGx and in genomic disease susceptibility research. Persons identified as having specific ADRs or poor therapy outcomes are the "cases." The frequencies of genotypes in "cases" are compared with those in concurrently sampled controls who have had comparable drug exposure but are free of problematic outcome. It is likely that, in the future, an acceleration in pharmacogenomic applications will be achieved by combining information from RCTs and observational studies in which there is no concurrent random assignment comparing a population without intervention to a population with intervention. This is a rapidly evolving field, and a sound understanding of different study designs is crucial in transforming pharmacogenomic discoveries into successful clinical applications.

Chapter Outline

16.1 Overview **323**
16.2 Variation: Importance of Race/Ethnicity **326**
16.3 Variation: CYP450 Phenotyping **327**
16.4 CYP450 Variation in Different Racial/Ethnic Populations—CYP450 Families **329**
16.4.1 CYP 1 329
16.4.2 CYP2C8/9/19 330
16.4.3 CYP2D6 333
16.4.4 CYP3A4 and CYP3A5 333
16.4.5 Other CYP450 Isoforms 335
16.5 Future Perspectives **337**
References **337**

16.1 OVERVIEW

Racial/ethnic differences in drug response lay at the foundation of pharmacogenetics and pharmacogenomics. "Pharmacogenetics" refers to research involving heredity, drug pharmacokinetics, and pharmacologic response. It began with epidemiologic investigations of the underlying reasons for differences in response to, or inherent toxicity of, drug therapy. As with many medical studies performed in this early era, careful observation guided much of the research. Early studies implicated demographic factors such as race/ethnicity and metabolic factors such as drug clearance as important variables related to response and/or toxicity.

In the 1950s, Clayman and Hockwald et al. observed different toxicity rates in the antimalarial primaquine among African Americans versus Caucasians [1,2]. In close chronologic proximity, Hughes and Vogel et al. showed different rates of isoniazid elimination due to slow and rapid individual acetylation phenotypes [3,4]. These early studies pointed to the fact that genetic factors were likely responsible for the observed differences in drug response or toxicity among different racial/ethnic groups. In 1959, Vogel coined the term *pharmacogenetics* [5].

Pharmacologic investigation is often categorized as pharmacokinetic or pharmacodynamic in nature. Much early work acknowledged genetic drivers of pharmacologic response, but focused on pharmacokinetics (also known as metabolic studies) instead of pharmacodynamics. This is likely due, in part, to the lack of molecular biology tools for pharmacodynamic study at the time. Additionally, there was a plethora of pharmacokinetic knowledge based on robust analytical techniques already in place by the 1950s. Indeed, receptor-mediated response was difficult to assess in the early days of pharmacology while robust chemical assessment tools were commonly available. The more recent revolution in molecular biology over the last few decades has made receptor isolation and functional characterization less of a monumental task. Other more recent advances in human genetics have spurred growth in research linking human genetics and pharmacology so that now we are attempting to achieve the goal of "personalized medicine." In addition to researchers, the discipline of pharmacogenetics has garnered interest from the mainstream. The goal of the U.S. Food and Drug Administration (FDA) Critical Path Initiative 2010 is to "continue improving risk–benefit balance of approved drugs by enhancing drug product label language to include pharmacogenetics, where appropriate" [6].

Hepatic CYP450 enzymes were identified as major determinants of variability in drug metabolism early in pharmacogenetics, and their importance has not waivered [7].

Handbook of Pharmacogenomics and Stratified Medicine. http://dx.doi.org/10.1016/B978-0-12-386882-4.00016-5
© 2014 Elsevier Inc. All rights reserved.

Genetic analyses of CYP450s began with identification of single-nucleotide polymorphisms (SNPs) in exons; they have expanded to identify other genetic variations such as promoter region polymorphisms and gene duplications.

Pharmacokinetic differences are important determinants of variability. They were the focus of early studies and continue to be studied today. In pharmacokinetics, it is not surprising that one of the first families of oxidative enzymes characterized was the hepatic CYP450 enzyme family. Approximately 75% of commonly used drugs are CYP450 substrates, with CYP450-mediated oxidation responsible for approximately 80% of oxidative drug metabolism [8,9].

The variability of human CYP450 is complicated by the induction and inhibition of CYP450s by other drugs and xenobiotic exposures in addition to the target drug. Host variability in enzyme activity, combined with induction and inhibition, can lead to significant drug–drug interactions [10,11]. Many drug labels contain CYP450 related pharmacogenetic information. Tables are presented later in the chapter with regard to specific CYP450 isoforms and their respective substrates and/or inhibitors for which pharmacogenetic information is available in the drug package insert [12].

Hepatic CYP450s are oxidative enzymes responsible for most human oxidative xenobiotic metabolism. This metabolism is known as phase I metabolism and is often followed by conjugation of polar adducts in a process known as phase II metabolism. CYP450s participate in biosynthesis of endogenous compounds, such as steroids. However, these biosynthetic CYP450s share a specific relationship with their respective substrates and do not participate in xenobiotic metabolism. CYP450 isoforms with sequence homologies of 40% or more are categorized into families, with subfamilies based on homologies of 55% or more. Human CYP450 isoforms fall into 18 family groups with 44 subfamilies. There exist 57 sequenced human genes and 58 pseudogenes [13]. Pseudogenes are CYP450 genes that lack functionality. Xenobiotic-metabolizing CYP450 isoforms belong almost exclusively to CYP families 1, 2, and 3. They are more promiscuous in their substrate specificity compared to the other human CYPs that have specific endogenous ligands.

The primary xenobiotic-metabolizing hepatic CYP450 isoforms are CYP1A2, 2A6, 2B6, 2C8, 2C9, 2C19, 2D6, 2E1, 3A4, and 3A5. These isoforms account for approximately 90% of CYP450-mediated drug metabolism [14]. CYP450s are heme-containing enzymes that catalyze different reactions, most commonly hydroxylation of their substrates. CYP450-mediated metabolism requires the cofactor NADPH and CYP450 reductase, and cytochrome b5 is required for maximal activity for several hepatic CYP450s. The CYP450 catalytic steps are still under investigation but are believed to proceed as follows:

1. Substrate binding near the heme iron in the ferric form.
2. Substrate binding displaces water from the heme iron.
3. The heme is reduced to its ferrous form via an electron transferred from CYP450 reductase.
4. Oxygen binds the heme iron.
5. A second electron is transferred to the bound oxygen.
6. An unstable peroxy intermediate forms.
7. A water molecule is released, generating compound I, which is a reactive iron (IV) oxo (or ferryl) radical that abstracts a proton and electron from the substrate.
8. An iron (IV) hydroxide complex is formed (known as Compound II).
9. Compound II rapidly recombines with the substrate, yielding the hydroxylated product [15]. After fully cycling through the oxidative reaction, there is a net input of one oxygen molecule, one substrate molecule, two protons, and two electrons, accompanied by the net release of a hydroxylated product and one water molecule (Figure 16.1).

Although CYP450s are expressed in every tissue of the body, hepatic CYP450s are the dominant CYP450 in regard to impact on the systemic pharmacokinetics of drugs and xenobiotics. CYP450 may be inducible, constitutively expressed, or both, and although much of its transcriptional apparatus has been delineated it is still an active area of research. The transcriptional apparatus of CYP450 varies by tissue along with expression. In the last few decades, research has shown that intestinal CYP450 is also a major determinant of xenobiotic pharmacokinetics, although to a lesser degree compared to hepatic enzymes.

Genetic polymorphisms in human xenobiotic-metabolizing CYP450 isoforms provide a major source of variability in CYP450 activity. Polymorphisms may exist that result in alteration of the physical CYP450's protein structure, gene copy number, or inducibility. An alteration in CYP450 protein structure may alter the protein's substrate affinity and catalytic activity. Often, polymorphisms result in alteration in functional phenotype. CYP450 2D6 is a CYP450 for which an individual may harbor multiple copies of CYP450 alleles. If the allele copies code for functional enzymes, multiple copies confer an enhanced metabolic phenotype. Newer polymorphisms have been identified in the promoter region of various CYP450 isoforms which alter their inducibility. They may enhance or interrupt transcription-factor binding, resulting in either enhanced or diminished inducibility, respectively (Figure 16.2).

Drug–drug interactions provide another source of variability through CYP450. Inhibition or induction of CYP450-mediated metabolism may occur because of concomitant exposure to multiple drugs or xenobiotics. Several mechanisms of CYP450 inhibition exist, but they all result in elevated exposure to drugs that would normally have been metabolized by the inhibited CYP450 isoform. Figure 16.3 illustrates the most common CYP450 inhibition mechanism via competitive inhibition. In this scenario, another

drug prevents a CYP450 substrate from being metabolized by occupying the CYP450 isoform active site and blocking substrate access. Effects due to CYP450 inhibition may be further complicated by shunting the bulk of substrate metabolism toward another less efficient CYP450 isoform. Although such scenarios are currently being experienced by patients today, they likely go unnoticed because of their complexity. These types of scenarios will also increase in the future as the prevalence of polypharmacy increases.

Of the approximately 75% of drugs that are CYP450 substrates, about 40% are metabolized by highly polymorphic CYP450 isoforms [9,16]. As drug manufacturers continue to develop new drugs, the percentage contribution of polymorphic enzymes involved in metabolism is expected to decline. CYP isoform-mediated metabolism characterization is a prerequisite for approval, and most manufacturers avoid new chemical entities that are polymorphic CYP450 substrates.

The reported percentage of CYP450 in liver varies likely because of population differences such as racial/ethnic makeup. Also, researchers have reported different specificities of antibodies used in Western blots [17,18]. Many literature reports about CYP450 activity are quite different from one another. Often apoprotein variability is reported in terms of fold activity for many CYPs, such as CYP3A4; however, *in vivo* activity is probably less variable. Even the highly polymorphic CYP2C19 showed only 21-fold *in vivo* interindividual variability [19]. A report by Galetin et al. showed CYP3A4 that fold activity differences in healthy individuals was only 4–10-fold compared to a 40–50-fold variability in apoprotein expression shown in other studies [18]. Table 16.1 summarizes the percentage contribution of hepatic CYP isoforms to total CYP450, the percentage of drugs metabolized by each isoform, and the *in vivo* (when reported) fold variability in isoform activity.

16.2 VARIATION: IMPORTANCE OF RACE/ETHNICITY

Race is a social construct. However, individuals tend to choose mates and reproduce within perceived racial/ethnic groups, and thus allele frequencies between groups may differ. In addition, haplotype blocks may vary by racial ethnic group because of differences in recombination sites. Racial/ethnic stratification may be necessary for the specific population genetic statistical approaches used by researchers. Hardy-Weinberg Equilibrium (HWE) calculations are a common way to assess whether a genotype is distributed as expected in a cohort. Genes not in HWE may be associated with a specific aberrant phenotype. Since HWE calculations assume random mating of individuals in a group, calculations of HWE require stratification of the different racial/ethnic groups being studied. These groups are often stratified in investigations where racial/ethnic differences might confound the disease–genetic relationship. However, self-reporting of race/ethnicity can be inaccurate in terms of genetic composition. This has led some investigators to identify ancestral genotype when working with genetically heterogeneous groups [24]. It should be kept in mind that the total impact of race/ethnicity on overall genetic variation is quite minimal. Only 5–15% of genetic variation is attributable to ancestral populations living on different continents [25].

TABLE 16.1 Variability in and Proportions of CYP450 in Human Liver

CYP	Isoform Contribution to Total Liver CYP450 (%)	Drugs Metabolized by CYP450 Isoform (%)	Isoform Fold Interindividual Variability
1A2	8–13	10	40–130
2A6	4–13	3	20–>100
2B6	2–10	4	20–250
2C8	7–12	5	2–9
2C9	10–20	10–20	3–27
2C19	4–13	5–13	21–28
2D6	1–2	15–25	>1000
2E1	2–9	3	20
3A4	20–50	36–50	40–50 but 4–10-fold in healthy populations
3A5	0.2–2	Expected to be similar to 3A4	ND

ND = not reported.

Source: Based on data reported in a number of references. See [14,16,18–23].

Regardless of type, investigators usually set up studies in similar ways. They attempt to create an "all things being equal" scenario except for the exposure, intervention, or genetic differences of interest. Since the genetic variation attributable to racial/ethnic groups is minimal, the genetic differences responsible for phenotypic differences among these groups become easier to identify. Small genetic differences may be harnessed to identify loci and genes of interest. Several researchers have used these differences in disease frequency to identify disease gene loci involved in complex diseases such as cancer [26].

Not surprisingly, genetic variability among racial/ethnic groups is not equal for all genes. Genes linked to environmental responses are more likely to vary by geography and thus differ by race/ethnicity. A major driver of such genetic variation is selection pressure. Genes that confer a survival advantage will be selected in a population residing in a particular environment. Xenobiotic-metabolizing CYP450s fall into this category because different CYP450 phenotypes can confer a survival advantage [27]. An example is a CYP450 metabolic phenotype that confers resistance to toxicity from ingestion of a plant endemic to a certain region [28]. Another example is a CYP450 phenotype that resists bioactivation of a fungal carcinogen endemic to tropical regions [29]. The observed racial/ethnic differences in both genotype and phenotype for xenobiotic-metabolizing CYP450s are likely due to ancestral environment–related positive selection.

In the case of xenobiotic-metabolizing CYP450 genes, there are many examples of allele and haplotype frequency differences in racial/ethnic groups. Many reports have thoroughly described such observations, which lie at the foundation of pharmacogenetics and pharmacogenomics. One recent example is given by the Pedersen et al., who investigated the frequency of the newly discovered CYP2C19 hyperfunctional allele CYP2C19*17 in Scandinavians and Ethiopians [30]. CYP2C19*17 appears to have higher frequency in Caucasians and some Eastern African groups. However, it was also found to be in linkage disequilibrium with the other fully functional CYP2C isoform alleles for 2C8 and 2C9. In other words, the hyperfunctional CYP2C19 allele is more likely to be found on the same chromosome as the wild-type CYP2C8 and CYP2C9 alleles. In haplotype predictions, 99.7% of Scandinavian CYP 2C19*17 carriers also possess CYP2C8*1 and CYP2C9*1 on the same haplotype. Out of 10 modeled haplotypes, the aforementioned haplotype was the second most frequent (19% frequency), following wild-type CYP2C8/9/19. The selective advantage of enhanced CYP2C function is unknown, but is surely not linked to modern drug exposures.

16.3 VARIATION: CYP450 PHENOTYPING

Assessment of human hepatic CYP450 activity involves both invasive and noninvasive methods. However, each method has inherent benefits and drawbacks. Invasive methods usually involve biopsy of hepatic tissue followed by *in vitro* reconstitution-system assays to assess drug-metabolizing capacity. Reconstituted metabolism systems used to identify CYP450 activity include harvested hepatocytes, hepatic tissue slices, or microsomal preparations from liver biopsy tissue. Besides being highly invasive, these approaches are subject to other problems in interpretation. Cultured hepatocytes begin to lose their ability to express CYP450 soon after being extracted. Microsomes maintain their metabolic activity for long periods of time, but require significant amounts of tissue for testing. Many reconstitution systems do not reflect variability due to other physiologic parameters that affect metabolism, such as hepatic blood flow. *In vitro*-to-*in vivo* extrapolation models are emerging that incorporate *in vitro* data on drug-metabolism reconstitution systems into highly predictive pharmacokinetic models. These models also incorporate physiologically based pharmacokinetic model parameters, such as hepatic blood flow, thus compensating for some of the limitations of reconstitution systems.

Substrate probes are drugs that undergo hepatic CYP450–mediated metabolism selectively via one CYP450 isoform. Once the probe is administered, elimination of specific metabolites may be monitored to characterize CYP isoform activity. Substrate probes can be used in both *in vitro* and *in vivo* reconstitution systems.

Avoidance of the need for invasive techniques on human subjects has been achieved by the use of animals in pharmacokinetic models. However, many animal species have dramatically different CYP450 activity at the isoform level. Exceptions include primates with robust CYP450-isoform sequence homology to humans such as cynomolgus monkeys. However, even these models do not replicate human pharmacokinetics perfectly for all drugs metabolized by certain isoform combinations. Currently, pooled human hepatic microsomes are readily available from vendors such as BD Biosciences; these pools are created from large numbers of individuals (e.g., n = 150), so they are reflective of population-level metabolism. Recombinant technologies allow transfection of human genes into other cell systems, such as BD Biosciences' baculovirus-transfected insect cells. These transfections allow for investigation of metabolism at the individual isoform level, providing a valuable tool for investigations of individual isoform–mediated metabolism and its contribution to overall metabolism. Other tools for identifying individual-isoform metabolism are CYP450 isoform–specific monoclonal antibodies, drug phenotyping probes, specific inhibitors, and specific inducers.

Drug-phenotyping probes were the first tools used to identify isoform-specific metabolism *in vivo*, and they are still effective tools. Before our current knowledge of isoform-specific CYP450 metabolism, pharmacokinetic studies showed differential metabolism among individuals due to genetic differences. Since these differences were difficult to observe if the metabolic clearance was attributable to multiple enzymes, investigators suspected a specific relationship between the substrate and the liver enzyme that metabolized it. Examples include Smith, Echelbaum, as well as Kupfer and Wendlunds' discovery of variability in the respective metabolic phenotypes of debrisoquine, sparteine, and mephenytoin due to polymorphisms in drug oxidative metabolic enzymes [3]. Variable activity for both debrisoquine and sparteine would later be attributed to CYP2D6 polymorphisms, while variability in mephenytoin activity is now known to be due to polymorphisms in CYP2C19. Not surprisingly, CYP2D6 and CYP2C19 are two of the most variable CYP450 isoforms expressed in human liver. Early studies showed that drug clearance serves as a noninvasive mechanism to probe enzyme function. Hence, these drugs were among the first drug "probes" of CYP450 activity. In 2004, Zhou et al. created a list of recommended CYP450 substrate probes after reviewing the literature and recommendations from the Committee for Proprietary Medicinal Products (CPMP), the FDA, the online drug interaction table by Flockhart, the European Federation for Pharmaceutical Sciences (EUFEPS), and the American Association of Pharmaceutical Sciences (AAPS) [16].

Establishing *in vivo* metabolic phenotypes is not straightforward. There is no strict agreement on phenotype nomenclature, nor are there clearly defined phenotype definitions. Phenotype is often assessed by administering different substrate probes and reporting metabolic ratios of different metabolites in different matrices at different times, using different sampling methods (extraction and detection). For example, one study might assess CYP1A2 phenotype by administering caffeine, detecting it and its major metabolite, paraxanthine, in urine obtained 12 h after dosing, extracting the parent and metabolite using solid-phase extraction, and quantifying them using HPLC with UV detection. However, another study might administer caffeine and then identify it, along with paraxanthine and other metabolites in plasma, 6 h after dosing, using liquid/liquid extraction and detecting it using HPLC MS/MS. Table 16.2 shows the major parameters that may vary when performing *in vivo* substrate-probe CYP450-phenotyping studies.

The FDA has provided recommendations to help manufacturers with pharmacogenomic submissions accompanying new drug applications, but it does not define a systematic approach for all CYP450 and it focuses on *in vitro* approaches [32]. Two reviews propose steps for validation of probe assays and cocktail assays [33,34]. In some studies, phenotypic groups are designated by different names or the number of phenotypic categories varies. According to several researchers, the distribution of metabolic phenotype must exhibit multiple modes if variant alleles that impact activity are present. Also, a phenotype directly determined by alleles that code for enzymes with different activity (such as wild-type and loss-of-function phenotype) should result in a histogram with at least two modes (a.k.a bimodal distribution). However, one could argue that phenotype is determined by a mixture of epigenetic, environmental, and multigenic factors. In this setting, the impact of known CYP450 variant alleles on metabolic phenotype may not drive a population into a clearly defined multi-modal distribution.

TABLE 16.2 Major Parameters in Phenotype Measurement

Substrate Probe	Metabolite(s) Measured	Matrix	Time (h)	Extraction Method	Sample Detection Method
Multiple probes for each CYP450 Isoform (e.g., caffeine or phenacetin for CYP1A2)	Most abundant metabolite (e.g., paraxanthine for caffeine)	Urine	Often varies by study (e.g., 4, 6, 8, 10, 12)	Solid-phase	HPLC with different detection (ex. UV)
	Several metabolites (e.g. paraxanthine, and 1,7 dimethyluracil)	Saliva		Liquid/liquid extraction	GC with different detection (ex. FID)
	All identified metabolites	Serum		On-column cleanup	GC MS or GC MS/MS
		Plasma		Direct injection	HPLC MS or HPLC MS/MS

Source: Based on data reported in Carillo et al. [31].

Many studies performed on the highly variable CYP2D6 and CYP2C19 describe four different phenotypic groups. However, it must be kept in mind that these groups are predicted genotypes based on known polymorphic alleles with altered function. The currently used names for the phenotypic groups for CYP2D6 and CYP2C19 are: Poor Metabolizer, Intermediate Metabolizer, Extensive Metabolizer, and Rapid Metabolizer. Other genotype category names used include Intermediate Metabolizer, Poor/Rapid Heterozygotes, Rapid Heterozygotes, and Ultra-Rapid Metabolizer.

Pharmacokinetic studies with various substrates have revealed either an additive or dominant mechanism of inheritance for the metabolizer traits. Phenotype is thus determined by the sum of allele functions or by carriage of an allele with profoundly altered activity, such as a lack of non-functional allele or a hyperfunctional allele. Initial pharmacokinetic and platelet-response studies with clopidogrel suggested that mixed carriers of the CYP2C19*2 (a loss of function allele) and CYP2C19*17 allele (a gain of function allele) have a metabolizer phenotype similar to homozygous wild type (*1) carriers [35]. However, later studies show that the phenotype manifests as lower activity than homozygous wild type carriers [36]. Figure 16.4 gives an example of the frequency of different genotypes for CYP2C19 along with respective predicted metabolizer phenotype for each. Readers should keep in mind that there is still significant variability of true phenotype in each predicted phenotype category. This is due to other factors such as induction, drug-drug interactions, or other genes that may impact pharmacokinetics such as transporters.

16.4 CYP450 VARIATION IN DIFFERENT RACIAL/ETHNIC POPULATIONS—CYP450 FAMILIES

Cytochrome P450 variations occur in different ethnic populations for most CYP450 isoforms. Clinically relevant variants are discussed to assist in identification of the impact of variants on the metabolism of specific drugs or xenobiotics when applied across many ethnic groups. Tables of drugs follow discussions of each CYP isoform. The drugs have either U.S. or European labeling comments and/or dosing recommendations because of pharmacogenetic-related impacts on drug pharmacokinetics (see Tables 16.3–16.6).

16.4.1 CYP 1

The human CYP 1 family includes CYP1A1, 1A2, and 1B1. CYP1A1 and CYP1B1 are important enzymes involved in xenobiotic metabolism but do not participate in much drug metabolism. Both are highly induced by Aryl Hydrocarbon receptor (AHR) binding ligands, such as dioxin, while also acting as metabolic enzymes for many of these substrates. CYP1A1 and CYP1B1 are expressed mostly in nonhepatic tissues which is why they are seldom studied in regards to drug metabolism [39]. The primary hepatic CYP 1 family enzyme is CYP1A2, which metabolizes approximately 10% of drugs including caffeine, ropinirole, theophylline, and tizanidine along with several important psychiatric medications including clozapine, haloperidol, olanzapine, and trazodone [40,41]. CYP1A2 is constitutively expressed, inducible, and subject to epigenetic regulation [42]. Drug inducers of CYP1A2 include albendazole, lansoprazole, omeprazole,

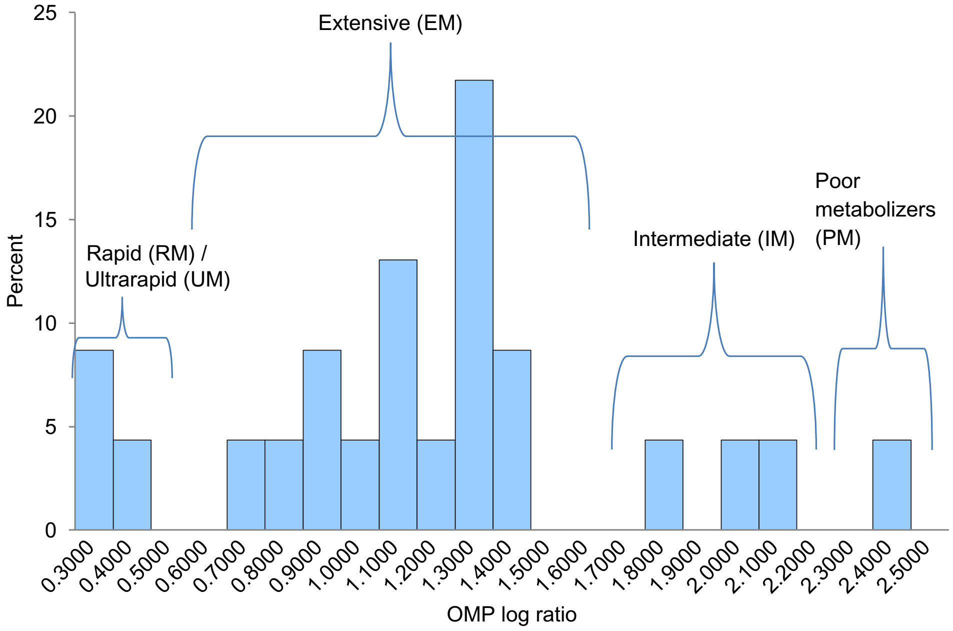

FIGURE 16.4 **Histogram of omeprazole metabolic ratios and proposed phenotype groups.** The histogram is based on a log [omeprazole]/[5-OH omeprazole] ratio measured 4 hr after a 30 mg CR omeprazole dose in saliva was extracted via molecular sieve filtration followed by HPLC MS/MS analysis (unpublished data, McGraw and Bichler 2013). CYP2C19 ultrarapid metabolizers possess two gain-of-function alleles (*17/*17); rapid heterozygotes harbor one *1 allele and one gain-of-function allele (for example, *1/*17); poor/rapid heterozygotes harbor one reduced-function and one gain-of-function allele (for example, *2/*17); extensive metabolizers are homozygous for the nonvariant *1 allele (*1/*1); intermediate metabolizers possess one *1 allele and one reduced-function allele (for example, *1/*2); and poor metabolizers harbor two reduced-function alleles (for example, *2/*2). *Source: Adapted from Scott et al.* [36].

and primaquine while contraceptives, fluvoxamine, and several quinolones are important inhibitors [40,41]. CYP1A2 activity varies widely (40–130-fold), due in part to its induction via several commonly consumed chemical exposures such as caffeine, charcoal barbecued meats, cigarette smoke, omeprazole, and oral contraceptives [43].

Genetics appear to be responsible for approximately 35% of variability in CYP1A2 activity [44]. CYP1A2 phenotypes are often categorized as extensive and poor while some studies report an ultrarapid phenotype. Metabolic ratio distributions have been described as bimodal or trimodal [45]. However, most studies do not report phenotypic groups beyond poor and normal (i.e., extensive) metabolizers. The frequency of poor metabolizer-phenotype status varies in different racial/ethnic groups. The two major haplotypes associated with it are known as CYP1A2*1C (rs2069514) and CYP1A2*1K (rs2069526, rs12720461, and rs762551). The CYP1A2*1C allele is commonly found in Asians (frequency ~25%) and is associated with decreased function, while the CYP1A2*1K allele (Asian frequency 0–4%) is associated with lower inducibility. Examples of poor metabolizer frequency in different populations are Australians (5%), Chinese (5%), and Japanese (14%). Overall, Asian and African populations have lower CYP1A2 activity compared to Caucasians [18]. The CYP1A2*1F allele (rs762551) appears to enhance the inducer function of CYP1A2 activity in carriers exposed to inducers such as cigarette smoke or omeprazole [46,47]. It is highly prevalent with a similar distribution across different racial/ethnic groups (frequency 60–66%) [47–49].

16.4.2 CYP2C8/9/19

Human CYP 2C-family enzymes share more than 80% sequence homology and exhibit both overlapping and

distinctive substrate specificity. They represent about 20% of liver CYP450 and metabolize about 25% of clinical drugs.

The least significant drug-metabolizing CYP2C isoform in terms of expression, CYP2C8, represents about 7% of total hepatic CYP450 and metabolizes around 5% of clinical drugs, including cerivastatin, several NSAIDs, paclitaxel, repaglinide, and thiazolidinediones. It is inhibited by gemfibrozil [51]. Several CYP2C8 polymorphisms believed to be clinically relevant include CYP2C8*1B, *2, *3, *4, and *5. Carriage of CYP2C8*2, a fairly prevalent allele, is believed to result clinically in impaired metabolic activity [52]. Conflicting results in the identification of CYP2C8 phenotype may be due to confounding factors such as participation of other enzymes (e.g., overlapping substrate specificity with CYP2C9) and linkage disequilibrium. Haplotype analyses may help alleviate these problems.

The CYP2C8*3 allele exhibits lower activity *in vitro*, but has been associated with higher clearance of CYP2C8 substrates *in vivo*. Rodriguez-Antona et al. showed increased clearance in the CYP2C8*3 allele containing haplotype carriers (haplotype B or haplotype D). Paclitaxel clearance was higher in haplotype B carriers, and repaglinide (a thiazolidinedione) clearance was higher in haplotype B or haplotype D carriers who were also heterozygous SLCO1B1 521T/T carriers (SLCO1B1 carriers have increased repaglinide uptake) [53]. Both drugs were metabolized to a lesser extent in the CYP2C8*1B-containing haplotype C carriers. The activity of the CYP2C8*4 allele is unknown, and the CYP2C8*5, *7, and *11 alleles are low frequency loss of function alleles.

The CYP2C9 alleles with impaired function observed clinically are 2C9*2, 2C9*3, and 2C9*5. CYP2C9 and 2C19 share 92% sequence homology [54]. CYP2C9 substrates include the angiotensin receptor antagonist losartan, the anticoagulant warfarin, the anticonvulsant phenytoin, the antidepressant fluvoxamine, the anti-inflammatories (celecoxib, diclofenac, flurbiprofen, and ibuprofen), fluvastatin,

nateglinide, and the sulfonylureas (glyburide, glibenclamide, glimepiride, and tolbutamide). Inhibitors of CYP2C9 include amiodarone, benzbromarone, bucolome, fluconazole, miconazole, and sulphaphenazole; it is induced by rifampicin [51]. Significant interest has focused on the effect of CYP2C9 polymorphism on warfarin activity and dosing.

Limdi et al. found an association between CYP2C9 variant allele carriers and lower warfarin dosing in Caucasian Americans, but not African Americans. They also found a significantly higher prevalence of variant genotypes in Caucasians versus African Americans (29.82% vs. 9.73%) despite the *5, *6, and *11 variants observed only in African Americans [55]. Scott et al. recently found a CYP2C9 allele labeled *8 with possibly lower functionality which may have a prevalence close to 9% in African Americans. They noted that addition of this allele to screening panels makes warfarin dose prediction more accurate in African Americans [56].

CYP2C19 is highly polymorphic, with at least 24 variant alleles of which many have no enzymatic activity. Important substrates for CYP2C19 include several benzodiazepines (diazepam, etizolam), the antiplatelet agent clopidogrel, proton pump inhibitors (lansoprazole, omeprazole, and rabeprazole), phenytoin, sertraline, and voriconazole. Inhibitors include ticlopidine, fluvoxamine, and voriconazole, while ritonavir, rifampicin, and rifabutin act as inducers [51]. The variants *2–*8 have been shown to be inactive [57]. They also distribute differently across racial/ethnic groups. Unlike other CYP450s, Caucasians and Africans share similar overall frequencies of poor metabolizer (PM) phenotype (1–8%), while Asians show a higher prevalence of PMs (13–23%) [21]. Phenotypes have been designated as extensive (two functional alleles), intermediate (one functional/one dysfunctional), poor (two loss-of-function alleles) and rapid (one or two gain-of-function alleles) (Table 16.7). The lack of functional CYP2C19 is a risk factor for adverse cardiovascular outcomes in patients taking clopidogrel because clopidogrel must be bioactivated by CYP2C19 for activity [35–37].

16.4.3 CYP2D6

CYP2D6 is responsible for metabolizing a number of important drugs containing amine functional groups, including members of the following psychotropic classes: anticholinergics/parasympathomimetics, antidepressants and monoamine modulating drugs (for example, serotonin 5-HT$_3$ receptor antagonists, monoamine oxidase inhibitors (MAOIs), serotonin reuptake inhibitors (SSRIs), and tricyclic antidepressants); antipsychotics (typical and atypical); opiates; and synthetic opiate derivatives. CYP2D6 also metabolizes several cardiac drugs from antiarrhythmic classes as well as beta blockers; some antifungals; and the antiestrogen tamoxifen. It is inhibited by celecoxib, cinacalcet, quinidine, several SSRIs (paroxetine and fluoxetine), and terbinafine [51].

A noteworthy attribute of CYP2D6 is that it is not inducible; rather, it is highly polymorphic with more than 100 variant alleles and ~200-fold variability in the metabolism of at least 100 drugs [58–61]. An attribute specific to CYP2D6 in comparison to other CYP450 enzymes is the presence of gene duplications that may confer an ultrarapid metabolizer phenotype. These polymorphisms are designated CYP2D6*(gene variant)XN, where XN refers to the number of gene copies. For example, CYP2D6*1X2 represents two copies of CYP2D6*1. The CYP2D6*1XN, *2XN, and *35XN alleles confer enhanced metabolic phenotype, while CYP2D6*17XN and CYP2D6*41XN show decreased activity and CYP2D6*4XN alleles show none.

Four potential CYP2D6 phenotypic subgroups exist. These groups are usually defined by the respective number of their functional alleles: ultrarapid (3), extensive (2), intermediate (1), and poor metabolizers (0). Most CYP2D6 polymorphisms result in an allele that lacks metabolic activity. However, the prevalence of poor metabolizer phenotypes varies by racial/ethnic group: Asians (~1%), Caucasians (5–10%), and Africans (0–19%) [58].

16.4.4 CYP3A4 and CYP3A5

The human CYP3A family includes CYP3A4, 3A5, 3A7, and 3A43, with CYP3A4 being the most abundant CYP450 isoform, representing up to 50% of liver CYP450. CYP3A4 represents approximately 20–50% of CYP450 content in liver and is responsible for 36–50% of drug metabolism. CYP3A5 is a closely related homologue that represents only 2% of CYP3A in Caucasian livers [9,22]. Examples of CYP3A4 substrates include many members of several drug classes, including benzodiazepines, calcium channel blockers, corticosteroids, ergot alkaloids, statins, transplant medications, and vinca alkaloids. Major inhibitors include azole antifungals, calcium channel blockers (diltiazem, verapamil), cimetidine, grapefruit juice, several macrolide antibiotics (erythromycin, clarithromycin, telithromycin, troleandomycin), nefazodone, and protease inhibitors. Inducers include rifampicin, rifabutin, phenobarbital, phenytoin, carbamazepine, efavirenz, and St. John's Wort [41].

Intestinal CYP3A4 also makes a major contribution to the metabolism of orally administered drugs because it contributes to first-pass metabolism [8]. Constitutive CYP3A4 variability is estimated at about 5-fold; however, illness, inhibition, and induction-related interactions can enhance variability up to 400-fold [8,18]. Other estimates across different populations project 40–50-fold variability [16]. Some estimates characterize variability in terms of apoprotein expression, which may overestimate *in vivo* variability for healthy subjects not experiencing drug

TABLE 16.7 CYP2C19 - Example of Genotypes, Frequency, and Predicted Phenotype

			CYP 2C19 Genotype		
Major Phenotypic Categories	Metabolizer Phenotype	Prevalence Range (%)	Normal Allele (*1)	Loss of Function (*2, *3, …)	Gain of Function (*17)
Poor	Poor	7(±8)		X,X

Note: 2C19 East Asian prevalence of poor metabolizer phenotype may be as high as 24%.

interactions. Population CYP3A4 metabolic phenotypes follow a unimodal distribution in most studies, which has been presented as evidence that CYP3A4 does not have a genetically determined poor or rapid metabolizer phenotype [45]. However, genetic contributions to variability may be obscured when other factors, such as enzyme induction via inducer exposure, are accounted for.

CYP3A4 and CYP3A5 share significant sequence homology and almost identical substrate specificity, but exhibit somewhat differing metabolic rates. CYP3A enzymes have a large active site and accommodate a great variety of substrates. Because of the polygomous nature of the active sites, substrates, including substrate probes, are often metabolized by both CYP3A4 and CYP3A5, but a few substrate probes appear to undergo selective metabolism. Erythromycin and quinidine are more specific CYP3A4 probes, while CYP3A5 preferentially metabolizes alprazolam alpha-hydroxylation, tacrolimus, and vincristine [62]. Caucasians exhibit lower CYP3A5 activity as a group because of a high prevalence of the splice variant, CYP3A5*3 [62], which is a highly prevalent polymorphism in all ethnic groups and causes the absence of functional CYP3A5 protein. CYP3A5*3 prevalence estimates in different groups are as follows: African Americans (32%), Caucasians (90–93%), East Asians (73%), Hispanics (65%), and South Asians (60%) [63–65].

Caucasians show enhanced CYP3A4-mediated metabolism in comparison to those of African ancestry [66]. Conversely, most Caucasians carry the loss-of-function CYP3A5*3 polymorphism. In most individuals, CYP3A5 has a minimal impact, as it represents only 2% of hepatic CYP450 in Caucasians. However, it may represent up to 50% of hepatic and intestinal CYP450 in some individuals [67]. A proposed cause for the differences in CYP450 activity may be the differential activity of CYP450 cofactors such as NADPH-dependent CYP450 reductase and cytochrome b5 (see Figure 16.1).

These cofactors are variable in different groups and may contribute to different CYP3A4 and CYP3A5 metabolic activities [68–70]. However, Elens et al. found carriage of the CYP450 oxidoreductase variant POR*28 was associated with lower *in vivo* CYP3A5 activity but had no impact on CYP3A4 activity [63]. They assessed CYP3A4/5 activity by administering midazolam, a nonspecific CYP3A4/5 probe, while assessing CYP3A4 specific activity with erythromycin, a specific CYP3A4 probe. They concluded that differences in CYP3A-mediated metabolism in Caucasians versus other racial/ethnic groups are not likely explained via CYP3A5-mediated metabolism or cofactor variability. Another major source of variability is interaction between CYP3A4/5 and drug transporters. Ogasawar et al. found that CYP3A5 expressors that are also in the MRP2 (transporter) high-activity group showed up to 2.3-fold lower dose–normalized trough tacrolimus concentrations. However, the researchers found no relationship with CYP3A4 variants [71].

As with most proteins and enzymes studied in pharmacogenetics, new functionally relevant polymorphisms and haplotypes of CYP450 enzymes are being identified. CYP3A4*1B is a CYP3A4 polymorphism that may alter CYP3A4 expression. It is an A→G transition at the −293 position in the gene promoter region that is highly prevalent in African Americans but not in Caucasians. The

CYP3A4*1B prevalence among different ethnic groups is Africans (76%), Caucasians (2–9.6%), Chinese and Taiwanese (0%), Hispanic Americans (9.3–11%), and African Americans (35–67%). Although it may provide much needed answers, the clinical impact of CYP3A4*1B is still under debate [72]. Other, yet to be discovered, candidate polymorphisms may explain differential CYP450 activity in different racial/ethnic groups as they are identified. A newly identified SNP, CYP3A4*20, results in a premature stop codon, thus coding for a truncated CYP3A with no activity [22]. This SNP has a relatively high prevalence among differing ethnic groups: Caucasian (6%), African American (26%), and Chinese (22%). The CYP3A4*22 variant allele is an intron 6 SNP found to influence RNA expression and statin, tacrolimus, and cyclosporin dose requirements [63,64,72]. Several other novel variants were also recently identified in a South African cohort, including CYP3A4*24, which is predicted to affect function; it was found at prevalences of 10.3%, 3.1%, and 3.2%, respectively, in Khoisan, Xhosa, and mixed-ancestry individuals [72]. More research is necessary before a clear understanding of the mechanism behind racial/ethnic differences in CYP3A4/5 is achieved. In addition to racial/ethnic metabolism differences, it should be noted that women have higher CYP3A activity than men, but this is offset by mens' larger hepatic mass [73,74].

16.4.5 Other CYP450 Isoforms

The CYP 2 gene cluster encodes several different CYP450 isoforms (CYP2A6, 2A7, 2A13, 2B6, 2F1, and 2S1) that are not often the focus of drug metabolism studies. Several factors explain this: they are minor contributors to hepatic CYP450 content, they have few known drug substrates, and/or they are expressed only in extrahepatic tissues. Although these human xenobiotic CYP450 enzymes are not highly expressed in liver, most are distributed in other tissues throughout the body. Pavek and Dvorak provide an excellent review of the distribution of these enzymes in extra-hepatic tissues [75]. Although CYP450s are not major sources of drug metabolism, they are involved in metabolism of other xenobiotics. Phenotypic differences in xenobiotic metabolism and differential metabolism of environmental xenobiotics, such as occupational and environmental contaminants, have also been reported among different racial/ethnic groups. Research regarding extrahepatic CYP450 metabolism has led to the belief that these isoforms may play a role in susceptibility and risk for diseases such as cancer [39].

CYP2A6 is an important human xenobiotic-metabolizing enzyme. However, it metabolizes only ~3% of drugs and is not the primary metabolic enzyme for most of these, likely because of its small active site and low overall hepatic expression. CYP2A6 is primarily expressed in liver (1–10% of liver CYP450) and nasal mucosa. It bioactivates several known procarcinogens such as aflatoxin B1 and 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (i.e., nicotine-derived nitrosamine ketone, NNK), while also acting as the major CYP isoform responsible for nicotine and tegafur metabolism. CYP2A6 inhibitors include isoniazid and methoxsalen as well as several endogenous catecholamines and steroids, while it is induced by phenobarbital and rifampicin [76]. CYP2A6*1A and *1B alleles are the most common CYP2A6 variants. The prevalence of CYP2A6*1A is 40% in Asians and 66% in Caucasians, whereas CYP2A6*1B is found in 40% of Asians and 30% of Caucasians [77,78].

More recently, four new dysfunctional alleles (*4G, *4H, *1B4, and *1L) have been discovered in individuals of African ancestry, with a combined prevalence of 7.3% [79,80]. African ancestry–specific polymorphisms are important because they help to explain the lower nicotine clearance observed in those of African descent when compared to those of Caucasian descent [81–83]. Nicotine metabolism differences are also important because African Americans suffer higher rates of smoking-related diseases [80]. As previously mentioned, CYP2A6 is important in the metabolism of environmental xenobiotics. Polychlorinated biphenyls (PCBs) are environmental contaminants that were banned from use in the 1970s but are still found in human tissues today. CYP2A6 was found to specifically metabolize one PCB congener, known as PCB congener 101, which is highly prevalent in the environment but should be rapidly metabolized in most humans [84]. PCB 101 was found at higher serum concentrations in African American women reporting exclusive African ancestry versus African American women of mixed race/ethnicity [85]. It was believed that higher PCB 101 levels may have been a marker of poor metabolism linked to those of African descent. This may be an environmental correlate to the lower nicotine metabolism in carriers of loss-of-function CYP2A6 polymorphisms.

CYP2B6 is highly polymorphic and highly inducible (20–250-fold variation), with 53 allelic variants described thus far [13,86]. Basal CYP2B6 expression in human liver is low, but is highly induced with relatively low hepatic expression compared to other CYP isoforms (~1–10% of liver CYP450) [87]. CYP2B6 variability among racial/ethnic groups is noteworthy for several reasons. Its phenotypic activity does not appear to vary by racial/ethnic group in men but is 3.6- and 5.0-fold higher in Hispanic women compared to Caucasian and African-American women, respectively [88]. CYP450 allele frequencies also vary highly among large racial/ethnic groupings such as Asians. For this reason, it is important to be more specific in terms of racial/ethnic stratification regarding it.

Important substrates for CYP2B6 include aflatoxin, bupropion, chlorpyrifos, cyclophosphamide, efavirenz, nevirapine, and nicotine [86,89]. It is inhibited by clopidogrel, mifepristone (RU486), selegiline, methadone, tamoxifen, ticlopidine, and thioTEPA, while it is induced by artemisinin antimalarials, carbamazepine, cyclophosphamide, efavirenz, hyperforin, metamizole, N,N-diethyl-m-toluamide (DEET), phenytoin, phenobarbital, rifampicin, ritonavir, and statins [87]. Several CYP2B6 SNPs may be present on one allele because of its high rate of polymorphism. The most common SNP present in multiple alleles is c.516G→T; this SNP is responsible for a loss-of-function phenotype and is often found in combination with c.785A→G [90]. As mentioned previously, there is a large amount of heterogeneity in the frequency of the c.516G→T allele in different Asian populations: Han Chinese (21%), Hong Kong Chinese (43%), Indian (39%), Japanese (14–20%), Korean (15%), Southern Chinese (35%), Taiwanese (14%), Thai (32%), Uygur Chinese (28%), and Vietnamese (27%) [91]. The activity phenotype of many CYP2B6 variants has not been characterized, and some variants appear to behave differently toward different substrates. CYP2B6*6 is a common variant (15–60% frequency) that confers significantly reduced activity *in vivo* attributable to aberrant splicing [92]. Many loss-of-function alleles have been identified; they include CYP2B6*2, *6, *7, *11, *15, *16, *18, *26, *27, and *28. Dysfunctional alleles have been shown to be present in more than 45% of individuals, but this figure varies widely by population. CYP2B6*18 is a loss-of-function allele prevalent in those of African ancestry (4–12%). A variant CYP2B6 genotype has been linked to altered pharmacokinetics of bupropion, cyclophosphamide, efavirenz, methadone, and neviripine [87].

CYP2E1 is a low-abundance hepatic CYP450 isoform (~5% hepatic CYP450) for which only two polymorphisms have been associated with altered *in vivo* activity [57,93,94]. Drugs metabolized primarily by CYP2E1 include chlorzoxazone, dacarbazine, enflurane, ethanol, halothane, isoniazid, sevoflurane, and theophylline; CYP2E1 is involved in toxicity of acetaminophen, ethanol, and styrene [95,96]. The CYP2E1*1D allele is associated with increased 2E1 activity in the presence of chronic ethanol ingestion and obesity [97]. CYP2E1*6 allele carriers who were alcoholics had significantly lower CYP2E1 activity [98]. CYP2E1 is located in the endoplasmic reticulum membrane, as are all CYP450s, but it is also located in the mitochondrial membrane. Induction of mitochondrial CYP2E1 increases reactive oxygen species generation and is thought to participate in the toxic effects of ethanol [99].

CYP450 pharmacogenetics. The listed descriptions give a brief idea of content, but most of the websites offer in-depth information beyond this.

16.5 FUTURE PERSPECTIVES

As mentioned previously, CYP450s are the primary phase I enzymes responsible for metabolizing approximately 75% of all drugs. Most of this metabolism is mediated by the xenobiotic-metabolizing, hepatically expressed CYP450 isoforms CYP1A2, CYP2C8/9/19, CYP2D6, CYP2E1, and CYP3A4/5. Early researchers identified differences in CYP450-mediated metabolism among racial/ethnic groups. Identification of the genetic determinants of these differences spawned the field of pharmacogenetics.

Today we continue to identify the genetic and environmental determinants of differences in drug response at the individual and group levels. Although race is a social construct, racial stratification is often a necessity in population genetic studies involving CYP450 genes. The contribution of interethnic genetic variation is minimal compared to interindividual variation. However, unstable genes linked to environmental circumstances, such as CYP450, vary dramatically among different racial/ethnic groups. Many examples of racial/ethnic differences in CYP450 allele frequencies and haplotype blocks have been identified. Not surprisingly, metabolic phenotype prevalences vary by race/ethnicity for most of the important CYP450 isoforms.

The wealth of pharmacogenetic data accumulated thus far regarding the aforementioned CYP450 isoforms has led to many drug-labeling notices and/or dosing recommendations for individuals with variant metabolic phenotypes who may be taking specific drugs. A barrier to their use is the lack of information regarding individual patients' metabolic phenotype. Scott et al. have provided an up-to-date list of providers of CYP2C19 genotyping, and the number of vendors offering such services is likely to increase [36]. Indeed, whole exome sequencing should become fairly common with an ever growing number of next-generation sequencing providers. However, in the case of CYP450 phenotype, exon sequencing may not provide complete answers because new clinically significant polymorphisms in nonexon regions such as the promoter region are being discovered.

Increased use of haplotype approaches in pharmacogenetics research should also prove to be beneficial. This is especially true for CYP450 isoforms that share loci, among them the CYP2C family. As more data are gathered, and as knowledge of individual pharmacogenetic information (e.g., metabolic phenotype) becomes more widespread, the goal of personalized medicine will become a reality. Enhanced knowledge of drug- and patient-specific pharmacogenetic data will allow prescribers to maximize drug efficacy for their patients while minimizing the risks of toxicity and side effects.

17.1 OVERVIEW

The goal of therapeutics is to achieve a definite beneficial effect with minimal adverse effect, and the approach to this has been through combining the principles of pharmacokinetics and pharmacodynamics. Pharmacokinetics (PK) is the branch of pharmacology that deals with the absorption, distribution, and elimination of drugs, while pharmacodynamics (PD) deals with the actions of drugs on the organism. PK governs the relationship between the drug dose and its concentration whereas PD relates the concentration to the effect; together PK/PD clarify a drug's dose–effect relationship. Since the 1950s there have been major advances in understanding the genetic basis of the interindividual variability observed in the pharmacokinetics, efficacy, and toxicity of various drugs. Recently, the European Medicines Agency (EMA) published guidance on the use of pharmacogenetics to investigate PK properties of new medicines [1] and PK pharmacogenetics feature in an increasing number of drug labels approved by the FDA [2]. Many pharmaceutical companies investigate the associations between PK gene variants and the observed interindividual pharmacokinetic and pharmacodynamic variability of drugs in early clinical development (phases I and II) [3]. In this chapter, we outline the basic principles of pharmacokinetics and summarize the progress in the pharmacogenomics of key pharmacokinetic systems.

17.2 PRINCIPLES OF PHARMACOKINETICS

PK studies are usually based on measuring the drug levels in blood and urine at different times following drug administration in order to understand how rapidly and for how long the drug appears in the target organ [4]. This involves mathematical modeling of data obtained from these studies around four domains: drug absorption (A), distribution (D), metabolism (M), and excretion (E). Together these are referred as ADME [4,5].

17.2.1 Absorption

Drugs are normally administered through various routes: orally, subcutaneously, intramuscularly, intravenously, rectally, or sublingually. Once a drug is administered, it is absorbed and distributed to different cells and organs. Drug absorption is generally defined as the rate and extent to

Handbook of Pharmacogenomics and Stratified Medicine. http://dx.doi.org/10.1016/B978-0-12-386882-4.00017-7
© 2014 Elsevier Inc. All rights reserved.

which the drug moves from its site of administration to its intended target (site) of action [6,7]. Absorption is a critical component in drug PKs, and several barriers must be overcome for a drug to reach its effect site. The rate and extent of absorption, as well as the time required to notice an observable effect, dictate the dose that should be administered [8].

Bioavailability indicates the proportion of the drug that passes into systemic circulation after administration, taking into account both absorption and local metabolic degradation [7]. Intravenous delivery provides 100% bioavailability, while an orally ingested drug may be incompletely absorbed by the GI tract before it reaches systemic circulation (around 75% of an orally administered drug is absorbed in 1–3 hours). In addition, the gastrointestinal lining expresses several cytochrome P450 enzymes and drug-efflux transporters (e.g., ATP-binding cassette, or ABC) that can decrease bioavailability [6,9].

Bioavailability depends on several factors, including the drug's physicochemical properties and formulation, first-pass metabolism, concomitant drug therapies, compliance, and disease state. The area under the curve (AUC) calculated from time zero to infinity following drug administration is an important PK parameter that measures the patient's "exposure" to a drug and depends on dose, bioavailability, and clearance [6]. The patient's plasma drug concentration time profile can be developed by measuring the plasma drug concentration at many time points and then estimating AUC, which is proportional to the absorbed fraction only when clearance is constant and the concentration is standardized.

Following linear kinetics, AUC is directly proportional to drug dose and inversely proportional to drug clearance. Therefore, the higher the clearance, the less time the drug spends in the systemic circulation and the earlier the decline in the concentration. As a result, the body's exposure to the drug and the AUC are smaller. Clearance is slightly dependent on the shape of the concentration time profile and is calculated by dividing the dose absorbed by the AUC [10].

Orally administered drugs are absorbed from the GI system and transferred to the liver via the portal vein before entering systemic circulation. The drug-metabolizing systems in the liver can thus exert a substantial effect on bioavailability; this is called first-pass metabolism or presystemic elimination. The larger the first-pass metabolism, the smaller the bioavailability of an orally administered drug. The liver drug metabolizing enzymes can be completely avoided by sublingual or buccal administrations or partially avoided by rectal administration [6]. Drugs that undergo extensive first-pass metabolism and cannot be administered orally (e.g., nitroglycerin) require alternative routes of administration, such as sublingual or intravenous. Drugs with extensive first-pass metabolisms can still be administered orally with higher doses. For example, a typical IV dose of verapamil is 1–5 mg, compared to the usual single oral dose of 40–120 mg.

First-pass metabolism is a major reason for recognizable differences in drug bioavailability among individuals, as even healthy people show considerable metabolizing differences in liver capacity. Moreover, in patients with severe liver disease, first-pass metabolism may be sharply decreased, leading to greater bioavailability [6]. Marked interindividual variations in terms of first-pass metabolism lead to unpredictable consequences. Examples of drugs that undergo significant "first-pass effect" are aspirin, morphine, levodopa, verapamil, salbutamol, and lidocaine [7,11].

17.2.2 Distribution

Once a drug has reached the bloodstream, it is distributed into the interstitial and intracellular compartments. As a general rule, the movement of lipophilic drugs is faster than that of hydrophilic drugs, and small lipophilic molecules distribute across cell membranes more easily than do large polar molecules [12–14]. Lipophobic drugs are primarily confined to plasma and interstitial fluids and generally do not go through the brain tissue after acute dosing. Hydrophilic drugs, such as the aminoglycosides, are mostly distributed into extracellular fluid, and their volume is affected by fluid retention or dehydration, both of which can happen in a number of renal diseases.

Passive diffusion, facilitated diffusion, and active transport are the three mechanisms involved in drug distribution across cell membranes [15]. Solute carrier (SLC) and ATP-binding cassette (ABC) transporters play an important role in active drug transport [16]. Cardiac output, regional blood flow, capillary permeability, lipid solubility, and plasma-protein binding determine the rate and amount of drug distributed into tissue [12].

Sites with high blood flow primarily receive greater amounts of a drug compared to sites with low or disturbed blood flow. Consequently, drug concentrations increase faster in organs such as the brain, heart, and kidneys as compared with skin, muscle, and bone. The structure and permeability of capillaries varies depending on the organ, and this affects how the drug is distributed. For example, capillaries in the kidney and liver sinusoids show more permeability as compared with the tight junctions between endothelial cells that line the brain capillaries, creating a relatively impermeable blood–brain barrier (BBB). The BBB allows only selective transport of lipophilic molecules and prevents passive entry of lipophobic/ionized molecules into the brain [12,13].

17.2.2.1 Plasma-Protein Binding

In blood, many drugs are bound to plasma protein. This binding is reversible with bound and unbound drug fractions in dynamic equilibrium. Any change in unbound-drug concentration is directly followed by a change in bound-drug concentration. Only free (unbound) fractions are able to cross membranes or interact with drug targets and are considered pharmacologically active. In general, the amount of a drug that is bound to protein depends on three main factors: free-drug concentration, binding site affinity, and protein concentration [17,18].

The most significant plasma-protein binding is to albumin, which is the major carrier of acidic drugs (e.g., warfarin, sulfonamides). Other plasma proteins, such as α1-acid glycoprotein, bind basic drugs. In addition, certain drugs may bind to proteins that function as specific hormone carrier proteins, such as the binding of estrogen or testosterone to sex hormone–binding globulin or the binding of thyroid hormone to thyroxin-binding globulin. For many drugs, more than 90% in the plasma is bound to a protein (e.g., warfarin, diazepam), whereas other drugs may have less extensive protein binding (digoxin and gentamicin). Because binding of drugs to plasma proteins such as albumin is nonselective, and because the number of binding sites is relatively large (high-capacity), many drugs with similar physicochemical characteristics can compete with each other and with endogenous substances for these binding sites, resulting in displacement of one drug by another and leading to an increase in its pharmacological activity or toxicity.

Changes in plasma-protein concentrations can also lead to variability in pharmacological effects of drugs, which are also affected by disease-related factors; for example, hypoalbuminemia secondary to nephrotic syndrome results in decreased drug binding, which increases the drug's unbound fraction of the drug. In addition, acute-phase reaction responses (e.g., cancer, arthritis) can lead to high levels of α1-acid glycoprotein and can enhance basic drug binding. Misinterpretation of plasma drug concentration measurements is a common problem that results from drugs competing for plasma-protein binding sites, as most assays do not differentiate unbound from bound drugs.

A number of drugs concentrate in body tissues at higher levels than those in extracellular fluids and blood; for example, the concentration of an antimalarial agent (quinacrine) in the liver can be many thousand times higher than that in the blood if the drug is administered for long periods. Reversible tissue binding of drugs regularly happens with proteins and phospholipids. Fractions of a drug in the body may be bound in this way and can act as a reservoir that prolongs drug action in the same tissue or at a distant site. Lipophilic drugs can accumulate in adipose tissue [12]. Halothane can concentrate in fat during long operations, and its slow release can cause postoperative prolonged central nervous system (CNS) depression. Tissue binding and drug accumulation may lead to local toxicity, as in the case of aminoglycoside antibiotic (gentamicin) accumulation in the kidneys and vestibular system [12].

17.2.2.2 Volume of Distribution

Volume of distribution (Vd), represents the apparent volume into which the drug is distributed to provide the same concentration as it currently is in blood plasma. It is calculated by the amount of the drug in the body divided by the plasma concentration [19]. Thus, Vd reflects the extent to which the drug is present in extravascular tissues but not in plasma. Lipid solubility can affect Vd, as highly lipid-soluble drugs have good cell penetration, resulting in high Vd. Plasma-protein binding, particularly to albumin, reduces the Vd, while tissue binding increases it [17].

Vd can be used to determine the size of a loading dose in order to quickly reach the required therapeutic plasma concentration, assuming that successful therapy is directly linked to the plasma concentration and that there are no adverse effects if a quite large dose is rapidly administered. In addition, Vd is helpful in predicting the initial maximum concentration for an IV bolus and can be used to predict the effectiveness of dialysis in treating drug intoxication during an emergency [18].

17.2.3 Metabolism

Once drugs have been distributed throughout the body, they are metabolized into more polar, inactive metabolites in order to eliminate them from the body. The lipophilic characteristics of drugs that promote their passage through biological membranes and subsequent access to their site of action also serve to hinder their excretion from the body. Metabolism includes two main processes: one, the molecule is made more lipophobic in order to reduce the possibility of reabsorption in the renal tubules; two, the molecule is conjugated to reduce its effect and increase its excretion. While for some drugs the metabolites have the actions of the parent drug (e.g., diazepam and its metabolite, nordiazepam), for others, the metabolite may result in toxicity (e.g., paracetamol). Also, a number of drugs are "prodrugs" (i.e., inactive) but transform into an active drug in the body. Prodrugs are often designed to improve oral bioavailability in cases where the intended drug is poorly absorbed through the gastrointestinal tract; for example, enalapril is hydrolyzed to the active compound enalaprilat [12].

Metabolizing enzymes are distributed in many tissues in the human body, with the highest levels found in GI tract tissues (e.g., the liver and the small and large intestines). The liver is the major metabolizing organ for both drugs and endogenous chemicals (e.g., cholesterol, fatty acids, and proteins). The small intestine also plays a vital role in drug metabolism, as most orally administered drugs become inactivated metabolically in either the intestinal epithelium or the liver before they reach systemic circulation [20]. Drug metabolism reactions are classified as either phase I or phase II.

17.2.3.1 Phase I Reactions

Drugs metabolized by phase I reactions usually lose their pharmacological activity, although there are some examples of enhanced or altered pharmacological activity. If not eliminated rapidly through urine, phase I reaction products can react with endogenous compounds to form a highly water-soluble conjugate [12].

Phase I reactions "functionalize" the drug for phase II, as they introduce a functional group—such as –OH, –COOH, –SH, –O–, or NH—which increases the polarity of the drug molecule and provides a site for phase II reactions. Phase I metabolic reactions include oxidation, reduction, and hydrolysis [20] (see Table 17.1).

Oxidations are the most common type of reaction and are catalyzed by the cytochrome P450 (CYP) system, which is located in the smooth endoplasmic reticulum. Metabolizing enzymes responsible for oxidation are mainly CYPs, alcohol dehydrogenase (ADH), aldehyde dehydrogenase (ALDH), dihydropyrimidine dehydrogenase (DPD), monoamine oxidase (MAO),

TABLE 17.1 Phase I and Phase II Reactions, Enzymes, and Substrate Drugs

Reaction	Enzymes	Drugs
Phase I		
Oxidation	N-dealkylation	Fentanyl, Buprenorphine, Morphine, Imipramine, Diazepam Codeine, Erythromycin, Tamoxifen, Theophylline, Caffeine, Methadone
	O-dealkylation	Codeine, Dextromethorphan, Indometacin,
	Aliphatic hydroxylation	Ibuprofen, Tolbutamide, Phenobarbital, Meprobamate, Cyclosporine, Midazolam
	Aromatic hydroxylation	Phenytoin, Phenobarbital, Propranolol, Ethinyl Estradiol, Amphetamine, Warfarin
	N-oxidation	Dapsone, Chlorpheniramine, Meperidine
	S-oxidation	Cimetidine, Chlorpromazine, Thioridazine, Omeprazole
	Deamination	Diazepam, Amphetamine
Hydrolysis		Modafinil, Salvinorin A, Carbamazepine, Procaine, Aspirin, Clofibrate Meperidine, Enalapril, Cocaine, Lidocaine, Procainamide, Indomethacin, Suxamethonium
Reduction		Prednisone
Phase II		
Glucuronidation	UDP-glucuronosyl transferases (UGT)	Morphine, Acetaminophen, Oxazepam, Lorazepam, UDP-Glucuronic
Sulphation	Sulfotransferases (SULT)	Paracetamol, Steroids, Methyldopa
Methylation	Methyltransferases (MT)	L-Dopa, Methyldopa, Mercaptopurine, Captopril
Acetylation	N-acetyltransferases (NAT)	Sulphonamides, Isoniazid, Dapsone, Clonazepam
Amino acid conjugation	Bile acid-coenzyme A:amino acid N-acyltransferase (BAAT)	Glycine
Glutathione conjugation	Glutathione-S-transferases (GST)	Paracetamol, Adriamycin, Fosfomycin, Busulfan

and flavin-containing monooxygenase (FMO) [20,21]. Oxidation via phase I enzymes adds or exposes a functional group, allowing phase I metabolites to act as substrates for the phase II conjugating enzyme [20]. The oxidation of a drug by the CYP system requires a P450 enzyme, molecular oxygen, nicotinamide adenine dinucleotide phosphate (NADPH), and a flavoprotein (NADPH-P450 reductase).

Hydrolysis is not limited to the liver but also takes place in various tissues. The main metabolic enzymes involved in drug hydrolysis are epoxide hydrolases (EH), esterases, and amidases [21]. Inactive prodrugs are converted rapidly to active metabolites mostly through an ester or amide linkage hydrolysis; for example, enalapril, the angiotensin-converting enzyme inhibitor, is quite inactive until it is transformed by esterase into its diacid metabolite (enalaprilat) [12]. Examples of drugs that undergo hydrolysis include carbamazepine, aspirin, meperidine, lidocaine, procainamide, and indomethacin [20].

Reduction reactions are much less common than oxidation reactions. The main metabolic enzyme involved in reduction is NADPH-CYP reductase [21]. A few drugs undergo reduction reactions, and some reductive reactions are important; for example, warfarin is inactivated by conversion of a ketone to a hydroxyl group by the CYP2A6 enzyme.

CYPs, FMO, and EH, in addition to some phase II conjugating enzymes, particularly Uridine 5′-diphospho-glucuronosyltransferase (UDP-glucuronosyltransferase, or UGT), are located mainly in the endoplasmic reticulum, while phase II enzymes are mostly cytosolic [20].

17.2.3.2 Phase II Reactions

Whereas various phase I reactions inactivate a drug biologically, phase II enzymes enable drug elimination by significantly increasing water solubility, abolishing pharmacological activity, and increasing molecular weight. Phase II reactions are generally biosynthetic (conjugation) reactions, such as glucuronidation, sulphation, acetylation, methylation, and glutathione conjugation [20]. These highly polar conjugates in general are inactive and are eliminated rapidly through urine and feces.

Phase II enzymes comprise a number of conjugating enzyme superfamilies, including the glutathione-S-transferases (GST), UGT, sulfotransferases (SULT), *N*-acetyltransferases (NAT), and methyltransferases (MT). Phase II reactions as a whole depend on catalytic reactions for cofactors such as UDP-glucuronic acid (UDP-GA) for UGT and 3-phosphoadenosine-5-phosphosulfate (PAPS) for SULT, which respond to the substrate functional groups. These functional groups are mainly formed via phase I CYPs. In cholestasis, toxic bile acids accumulate in hepatic cells, leading to their damage and functional impairment. Glucuronidation, which is catalyzed by UGT enzymes, is considered an essential metabolic pathway for hepatic bile acids [20,22].

17.2.3.3 Non-CYP450 Enzymes

Non-CYP450 enzymes play a vital role in both the metabolism and the elimination of several drugs; for example, UGT, SULT, thiopurine S-methyltransferase (TPMT), DPD, NAT, and GST have been indentified for their clinical significance [23].

UGTs are membrane-bound enzymes found in the hepatic endoplasmic reticulum and various other extrahepatic tissues [21]. They involve a superfamily of vital proteins that catalyze the glucuronidation reaction on a wide range of structurally different endogenous and exogenous compounds. UGTs catalyze the transfer of the glucuronic acid group of uridine diphosphoglucuronic acid to the functional group (e.g., hydroxyl, carboxyl, amino, sulfur) of a specific substrate [24].

SULTs are localized in the cytosol and catalyze the transfer of the sulfonyl group from the cofactor PAPS to the nucleophilic sites of a range of substrates, including hormones and drugs. In humans, 11 SULT isoforms have been recognized and have been classified into four main groups based on evolutionary projections (SULT 1, 2, 3, and 4) [20,21]. They play a significant role in human homeostasis. For instance, SULT1B1, which is mostly expressed in the skin and brain, is responsible for cholesterol and thyroid hormone catalysis [20].

TPMT is recognized for its important role in the metabolism of thiopurine drugs (e.g., 6-mercaptopurine (6-MP), azathiopurine (AZA), and 6-thioguanine) and is catalyzed through the s-methylation of aromatic and heterocyclic sulfhydryl [21]. AZA and 6-MP are used to treat inflammatory bowel disease and autoimmune disorders such as systemic lupus erythematosus and rheumatoid arthritis. 6-MP is also used for the treatment of childhood acute lymphoblastic leukemia (ALL). 6-thioguanine is used to treat acute myeloid leukemia (AML), and since TPMT is responsible for the detoxification of 6-MP, any deficiency in it can result in severe toxicities in patients taking those drugs [20,25]. DPD is the rate-limiting enzyme in pyrimidine and 5-fluorouracil (5-FU) degradation. 5-FU is commonly prescribed to treat GI malignancies, and DPD deficiency can increase concentrations of bioavailable 5-FU anabolic products, leading to 5-FU–related toxicity [26].

GST catalyzes glutathione conjugation to a broad range of endogenous metabolites and drugs. Human GSTs are classified into three major families: cytosolic/nuclear, mitochondrial, and microsomal. They also have nonenzymatic functions, as they work as regulators of cell signaling and the post-translational modification pathway in response to stress, growth factors, DNA damage, cell proliferation, cell death, and other processes that eventually lead to tumor growth and drug resistance. Because of their functionalities, GSTs are seen as significant determinants of cancer susceptibility, therapeutic response, and prognosis [20,21,27].

NATs are responsible for the metabolism of both drugs and environmental compounds that contain an aromatic amine or hydrazine group. NATs catalyze the transfer of an acetyl group from acetyl coenzyme A to arylamines, arylhydroxylamines, and arylhydrazines [20,21].

17.2.3.4 *Enzyme Induction*

The pharmacological effect of a drug is dependent on its concentration at its site of action, which is partly dependent on its metabolism rate. Any changes in this enzyme activity can affect drug action. Enzyme induction can be defined as the increased synthesis (higher amount) or decreased degradation (increased activity) of enzymes that occurs as a result of the presence of an exogenous substance [20,28]. It is usually associated with a reduction in drug efficacy but may also change the toxicity of particular substances. CYP3A4 plays a role in the metabolism of about 50% of the drugs that are currently prescribed. Induction of CYP3A4 by rifampicin can increase oestrogen metabolism, thus reducing the effectiveness of birth control pills.

Certain drugs can increase the rate of synthesis of CYP450 enzymes; consequently, this enzyme induction can enhance the clearance of other drugs. Generally, such induction needs exposure to the inducing agent for more than a week before effects can be observed [28]. Clinical studies have shown that carbamazepine, phenytoin, and rifampicin are the most potent enzyme inducers in clinical use as they produce many clinically significant drug interactions mainly associated with increases in the metabolism of CYP2C9, CYP2C19, and CYP3A4 substrates (see Table 17.2). However, enzyme induction is not limited to the administration of prescription drugs. St. John's Wort, an herbal medicine, can also induce metabolizing enzymes, as can tobacco, which induces a CYP1A2 substrate, such as theophylline [29].

17.2.3.5 *Enzyme Inhibition*

Enzyme inhibition refers to a decrease in enzyme-related processes, enzyme production, or enzyme activity. A number of clinically important interactions between drugs result from CYP450 inhibition. CYP450 inhibitors are different in their selectivity toward enzymes and are classified by their mechanisms of action. Some drugs are potent competitive inhibitors and compete for the active site, but they are not a substrate for the enzyme (e.g., quinidine and CYP2D6), while other drugs are noncompetitive inhibitors (e.g., ketoconazole and CYP3A4). Enzyme inhibition can cause many adverse drug interactions that tend to happen more rapidly (within a couple of days) than those seen with enzyme induction, as they occur once the concentration of the inhibiting drug becomes high enough to compete with the affected drug. Examples of enzyme-inhibiting agents are cimetidine, erythromycin, ciprofloxacin, and isoniazid.

In certain cases, enzyme inhibition can cause potentially serious adverse events; for example, ketoconazole reduces the metabolism of the CYP3A4 substrate (terfenadine), resulting in a prolonged QT interval and torsades de pointes. As with enzyme induction, enzyme inhibition is not limited to drug interactions [30]; for example, grapefruit juice (a CYP3A4 inhibitor) can cause clinically significant interactions with many drugs, such as midazolam, simvastatin, and terfenadine. Resulting in much higher plasma concentrations of the inhibited drug than intended, enzyme inhibition can be a major safety issue, such as in co-administration of ketoconazole or ritonavir with midazolam, which increases midazolam plasma exposure (AUC) by 15–20 times—a condition that should be avoided [8].

17.2.4 Excretion

Drugs are eliminated from the body through two main mechanisms—liver metabolism and renal excretion. Some drugs are excreted in insignificant amounts via other routes, such as sweat, saliva, and tears, and elimination through these routes depends mostly on nonionized lipophilic diffusion through the epithelial cells of the glands and on urine pH [12].

17.2.4.1 *Renal Excretion*

The kidney is the principal organ of excretion for a drug and its metabolites. Drugs that are water soluble are mostly excreted unchanged through the kidneys. Lipid-soluble drugs are not eliminated efficiently by the kidneys and first need to be metabolized to more polar products. Renal disease influences the excretion of particular drugs. The extent to which excretion is impaired can be deduced by measuring creatinine clearance. Drug and metabolite excretion in urine includes three different processes: glomerular filtration, active tubular secretion, and passive tubular reabsorption; changes in kidney function in general affect all three processes to a similar degree [12].

Glomerular filtration is the most common route of renal elimination. The amount of drug entering the tubular lumen through filtration depends on the glomerular filtration rate (GFR) and the level of plasma binding of the drug. Only unbound drugs are cleared by filtration; protein-bound drugs remain in circulation, where some of them dissociate to restore equilibrium. The size of the molecule is the only limiting factor at this step. In relation to filtered drugs, it is expected that great declines in renal function, as reflected by a decreased GFR, lead to drug accumulation, and therefore renal patients may need dose adjustments. However, for actively secreted drugs, GFR is less important than renal plasma flow [31].

TABLE 17.2 Cytochrome P450 Enzymes, Substrates, Inducers, and Inhibitors

Enzymes	Substrates	Inducers	Inhibitors
CYP2D6	Timolol, Metoprolol, Carvedilol, Fluoxetine, Paroxetine, Tricyclic antidepressants, Propafenone, Flecainide, Codeine, Phenformin, Codeine, Debrisoquine		Cimetidine, Quinidine, Halperidol, Bupropion, Fluoxetine, Paroxetine, Perhexaline, Cinacalcet, Doxepin, Duloxetine, Flecainide, Moclobemide, Quinine, Terbinafine, Sulphaphenazole, Benzoflavone, Troleandomycin, Ritonavir, Chlorpromazine, Miconazole, Diphenhydramine, Ketoconazole, Methadone, Nicardipine, Sertraline, Venlafaxine, Tricyclic antidepressants
CYP2C19	Omeprazole, Mephenytoin, Phenytoin	Rifampicin, Phenobarbital, Lopinavir/Ritonavir, St John's wort	Omeprazole, Fluconazole, Fluvoxamine, Ticlopidine, Clarithromycin, Fluoxetine, Moclobemide, Moriconazole, Diethyldithiocarbamate, Cimetidine, Ketoconazole
CYP1A2	Caffeine, Paracetamol, Tacrine, Theophylline	Phenytoin, Tobacco smoke, Phenobarbital, Beta-Naphthoflavone, Rifampin	Cimetidine, Ranitidine, Ciprofloxacin, Fluvoxamine, Ethinylestradiol, Interferon Alpha-2b, Methoxsalen, Sulphaphenazole, Benzoflavone, Troleandomycin, Furafylline
CYP2E1	Alcohol, Paracetamol	Isoniazid, Phenobarbital, Rifampin	Tetrahydrofurane, Diethyldithiocarbamate, Disulfiram, Sulphaphenazole, Benzoflavone, Quinidine, Troleandomycin
CYP2C8	Paclitaxel, Repaglinide, Rosiglitazone, Pioglitazone, Troglitazone, Amiodarone, Chloroquine, Amodiaquine, Verapamil, Ibuprofen, Ofluvastatin, Amitriptyline, Perphenazine, Diclofenac, Gallopamil, Omeprazole, Carbamazepine	Phenytoin, Rifampicin	Sulphaphenazole, Benzoflavone, Quinidine, Troleandomycin
CYP2C9	Warfarin, Phenytoin, Glipizide, Losartan, Ibuprofen, Tolbutamide	Rifampin Phenobarbital	Fluconazole, Sulphaphenazole, Benzoflavone, Quinidine, Troleandomycin, Ketoconazole, Amiodarone, Phenytoin
CYP3A	Calcium Channel Blockers, Antiarrhythmics (Lidocaine, Quinidine, Mexiletine), HMG-Coa Reductase Inhibitors, Cyclosporine, Tacrolimusindinavir, Saquinavir, Ritonavir, Nifedipine, Simvastatin	Bosentan, Rifampicin, Carbamazepine, Efavirenz, Phenobarbital, Modafinil, Phenytoin, St John's Wort, Clotrimazole, Ritonavir, Sulfinpyrazone	Erythromycin, Clarithromycin, Itraconazole, Ketoconazole, Lopinavir/Ritonavir, Ritonavir, Saquinavir, Saquinavir/Ritonavir, Voriconazole, Grapefruit Juice, Fluconazole, Amiodarone Cimetidine, Fluvoxamine, Diltiazem, Cyclosporin, Imatinib, Verapamil, Atazanavir/ Ritonavir, Atazanavir, Aprepitant, Sulphaphenazole, Benzoflavone, Quinidine, Troleandomycin, Diltiazem, Itraconazole
CYP2A6	Coumarin, Halothan, Methoxyflurane, Valporic Acid, Disulfiram, Losigamone, Letrozole	Phenobarbital, Rifampin	Methoxsalen, Diethyldithiocarbamate
CYP2B6	Cyclophosphamide, Methadone	Phenobarbital, Rifampin, Clotrimazole, Ritonavir, Sulfinpyrazone	Ritonavir, Efavirenz, Nelfinavir

Passive reabsorption in the distal tubule occurs only with unionized (lipid-soluble) drugs. Urine PH determines whether weak acids and bases are reabsorbed, and this in turn determines the degree of ionization. If renal function is impaired, for instance, by disease, the clearance of drugs that usually undergo renal excretion is decreased. Tubular reabsorption follows the role of passive nonionic diffusion and depends on both urinary pH and the drug's pKa. A pH that prefers the nonionized state of a drug increases both its lipophilicity and passive reabsorption across the tubular membrane. The extent of passive reabsorption also depends on urinary volume. The clinical relevance of renal tubular reabsorption relates generally to the disease effect on the process [31,32].

Active secretion in the proximal tubule is predominant in that the proximal convoluted tubule can actively secrete some compounds—mostly weak acids and bases—into the lumen of the nephron. Actively secreted drugs accumulate in patients with reduced renal function, as renal blood flow and GFR generally also decrease. The SLC transporters, which include organic cation transporters (OCTs) and organic anion transporters (OATs), are involved in active transport of many endogenous substances and drugs [32]. Actively secreted drugs are subject to competition for transport, so there are some concerns with particular clinical conditions in which co-administered drugs inhibit transport, which can expose patients to high drug concentrations [31]. As about 80% of a drug delivered to the kidney is subjected to the carrier, tubular secretion is probably the most efficient mechanism of renal drug elimination. A number of organic acids are actively secreted (e.g., penicillins, probenecid), as well as quite a few diuretics (e.g., furosemide, thiazides) and different conjugates (e.g., glucuronic acid, sulphate). Some organic cations are also secreted, such as morphine and amiloride.

17.2.4.2 Biliary Excretion

Liver cells transfer different substances, and bile excretion is a main route of excretion for a small number of drugs (e.g., cromoglycate) and a larger number of drug metabolites (e.g., morphine glucuronide). Drug conjugates are excreted into the bile and later released into the intestines, where they are reabsorbed into the body (enterohepatic circulation). Enterohepatic circulation has important clinical consequences, as it prolongs the drug effect and increases its plasma half-life ($t_{1/2}$). While some drugs are excreted mostly unchanged in bile (e.g., vecuronium), other drugs are excreted in bile after deacetylation, which retains their biological activity and stops their reabsorption. Drugs pass from plasma to bile via transport systems similar to renal tubules, such as OCTs, OATs, and P-glycoproteins.

17.2.5 Half-Life

The half-life ($t_{1/2}$) is one of the simplest PK parameters to calculate. It is the time taken for a drug concentration to fall to half of its original value, measured in hours. However, not only does it determine the time needed for drug concentrations to fall to immeasurably low levels following a single bolus; it is also the main determinant of the time required to achieve steady-state plasma concentrations (Css) after any changes in dose. When a drug is administered chronically and its amount administered per unit time equals the amount eliminated per unit time, this situation represents a steady state. While Css is stable in a continuous IV infusion, it varies during the dosing interval in chronic oral administration although the profile of time-concentration between dosing intervals is still stable.

The $t_{1/2}$ is related to elimination rate constant, clearance, and Vd. The "initial" concentration achieved after a single IV bolus, then, decreases by a constant amount per unit time as the drug is eliminated from the body. The parameter that describes this rate of decline is the elimination rate constant (k), and it depends on both clearance and volume of distribution. Clearance measures the ability of the body to eliminate a drug; therefore, as clearance decreases (e.g., with disease), $t_{1/2}$ is expected to increase. However, this kind of relationship is applicable only when the disease does not affect the Vd; for example, diazepam $t_{1/2}$ increases with patient age, but it is the volume of distribution that changes, not the clearance [12,18]. The $t_{1/2}$ represents the time taken to eliminate a drug and the time taken for the drug to accumulate to a steady state with multiple dosing or during a constant-rate infusion. This takes about 4–5 $t_{1/2}$ (when starting from zero). Drug concentration data are generally plotted against time. A drug achieves 50% of its Css after one $t_{1/2}$, 75% after two $t_{1/2}$, 88% after three $t_{1/2}$, 94% after four $t_{1/2}$, and 97% after five $t_{1/2}$.

$t_{1/2}$ is an important determinant of dose frequency and time required to achieve Css; however, it provides little information about differences in dose requirements associated with clinical conditions or diseases. For instance, a change in $t_{1/2}$ might reflect a change in Vd or clearance or both. In the same way, if both clearance and volume change in proportion, the $t_{1/2}$ may be unaltered although average steady-state concentrations may change. Clearance and volume should therefore be calculated individually whenever possible [18,33].

In a number of diseases, clearance and distribution volume can be affected by changes in protein binding, resulting in unpredictable $t_{1/2}$ changes. For example, in patients with acute viral hepatitis, tolbutamide $t_{1/2}$ exhibits enhanced clearance which is unexpected. This occurs because the disease changes both plasma and tissues protein binding, does not affect volume of distribution, but increases clearance because free drugs are present in the bloodstream in higher concentrations. Although it can be a poor indicator of drug elimination from the body, $t_{1/2}$ does give a good indication of the time required to reach a steady state whenever a drug regimen is initiated or changed, the time needed for a drug to be cleared from the body, and a means to predict the appropriate dosing interval [12,17].

17.2.6 Clearance

Clearance (CL) is the most important concept to consider when designing a rational regimen for long-term drug administration. CL (expressed as volume/time) describes the volume of fluid that is completely cleared of drug per unit time, mainly through hepatic metabolism and renal excretion [12]. While elimination $t_{1/2}$ determines the time required to achieve Css, the level of that steady state is determined through CL and dose alone. If the drug is given for long enough, the amount of drug eliminated from the body during one dosage interval is equal to the amount of drug that enters the systemic circulation during each dosage interval. This is known as a steady state. CL depends essentially on liver and/or kidney efficiency to eliminate a drug, and it varies in certain diseases that affect those organs or the blood supply to them. In a stable clinical situation, CL remains constant and is directly proportional to dose rate. The clinical importance of this is that, for most drugs, if the dose rate is doubled, the $Css_{average}$ doubles, and, if the dose rate is halved, the $Css_{average}$ is halved.

The concept of CL is very useful in clinical PKs because its value for certain drugs is generally constant over the clinically encountered concentration ranges. Drug elimination systems, such as metabolizing enzymes and transporters, are usually not saturated; therefore, the absolute elimination rate is basically a linear function of the drug's concentration in plasma. To be precise, the elimination of most drugs follows first-order kinetics, where a constant fraction of drug in the body is eliminated per unit of time. If the elimination mechanisms of a particular drug become saturated, the kinetics move toward zero-order kinetics, in which a constant amount of drug is eliminated per unit of time. In such situations, CL changes with drug concentration [12].

It is vital to understand that CL does not indicate how much of a drug is being cleared; rather, it indicates the volume of blood or plasma from which the drug would have to be totally removed to account for the CL. The CL by different organs (GI tract, kidney, liver, and other organs) is additive. Diseases, drug interactions, or even genetic variants that decrease the activity of drug-metabolizing enzymes or mechanisms of execration may decrease CL; consequently, a dose adjustment to avoid drug toxicity is required. On the other hand, a number of drug interactions and genetic variants increase CYP expression, and therefore increased drug dosage might be required to maintain a therapeutic effect [12].

17.2.7 Zero- and First-Order Kinetics

The hallmark of first-order (linear) kinetics is the proportionality between dose rate and Css. Most drugs show first-order kinetics, where a constant fraction of drug in the body is eliminated per unit time. Linear kinetics explains that the decrease in drug levels in the body is dependent on the plasma concentration (a concentration-dependent process). The higher the drug concentration, the larger the absolute amount of drug eliminated per unit time. Therefore, the rate of elimination is proportional to the amount of drug in the body, while CL remains constant. Generally, for drugs with first-order kinetics, Vd, $t_{1/2}$, k, and CL are all interrelated [12].

However, if the elimination mechanisms of a particular drug become saturated, the kinetics move toward zero-order (nonlinear) kinetics, in which a constant amount of drug is eliminated per unit of time. Various drugs follow zero-order kinetics at high or toxic concentrations. Metabolism in general, which involves particular enzymes, is one of the most important elements contributing to a drug undergoing zero-order kinetics. When metabolism enzymes reach a point of saturation, the rate of elimination does not increase in response to a concentration increase but rather becomes constant (a concentration-dependent process).

Common examples of drugs that follow nonlinear kinetics are aspirin, phenytoin, alcohol, heparin, and ethanol. The $t_{1/2}$ is not constant for zero-order reactions, but rather depends on concentration. The higher the concentration, the longer the $t_{1/2}$. The clinical significance of nonlinear kinetics is that any small increase in dose can cause a large increase in concentration. This is mainly important when toxic side effects and concentration are strongly related, which is the situation with, for example, phenytoin [12].

17.3 ADME: PHARMACOGENOMICS

As discussed previously, there are many sources of variation in enzyme activity; age, enzyme induction or inhibition, and diseases (especially of the liver) are among them. Variation in the DNA sequence of genes encoding enzymes can abolish, reduce, or increase the expression and activity of an enzyme, and this can manifest as the "metabolizer" phenotype in an individual. Individuals who are homozygous for the two alleles coding for "normal" enzyme function are termed extensive metabolizers (homozygous EM or "wild-type"); those who are homozygous with two variant alleles resulting in inactive or absent enzymes are "poor metabolizers" (PM); those who are heterozygous manifest an intermediate metabolizer (IM) phenotype with reduced function (heterozygous EM). Intermediate and extensive metabolizers are often collectively referred as extensive metabolizers, especially in studies in which metabolizer status is assigned using phenotype.

Gene duplication or multiplication, as, for example, seen in *CYP2D6*, can result in "ultrarapid metabolizer" (UM) phenotype. Standard drug doses achieve normal concentrations and effect in homozygous EMs (which usually make up the largest proportion of the population), but they may be toxic in PMs (possibly in heterozygous EMs or IMs) and ineffective in UMs, who may require a higher dose to achieve therapeutic effective drug concentrations [9,21,34].

In general, the most important factor affecting drug action is the AUC at the site of action, reflecting the "metabolizer" phenotype; AUC is the best pharmacokinetic end point for the assessment of pharmacogenetic effects. However, even if there is a clear association between concentration and drug effect/toxicity, there are multiple factors that determine the clinical relevance of a functional polymorphism in a drug metabolizing gene [34]. These are summarized here:

- Clear association between concentration and drug effect/toxicity. Genetic variation that affects the functioning of the drug metabolizing gene can affect the AUC and hence can predict drug effects.
- The clinical significance of a genetic variant depends on the drug's therapeutic index (the ratio between dose effectiveness and safety). A high therapeutic index indicating that a drug is safe over a wide range of concentrations and variations due to genetics may be irrelevant, whereas a low therapeutic index indicates that minor variations in drug concentration, such as from polymorphisms, may be important.
- If the drug effect is mediated by multiple active moieties, the relevance of genetic variation is diminished. For example, if the product of the drug–enzyme reaction is an active metabolite with activity similar to that of the parent molecule, an altered ratio of parent drug to metabolite (through polymorphism) may have little clinical effect.
- If a drug is metabolized or eliminated by multiple pathways, total ablation of one pathway (as in a PM) may result in minimal alteration of overall drug concentrations and hence have minimal effect.
- Sometimes enantiomers have different pharmacological activity and pathways of elimination. This is called stereoselective metabolism.
- Phenocopying is the conversion of a patient from a phenotypic normal metabolizer into a slow metabolizer as a result of inhibition of the enzyme by another drug or by itself ("autophenocopying"). This can result in a reduction in a trait's variation in a population. For example, all patients chronically taking a drug are poor metabolizers either because of their genotype or because of autophenocopying. Phenocopying sometimes explains why differences between PMs and EMs are less at steady state than after single doses.

17.3.1 CYP450 Enzymes

The major causes of interindividual and intraindividual variability in CYP activity are environmental factors (inducers and inhibitors), biological factors (gender, disease, and circadian rhythms), and genetic polymorphisms in CYP450 genes and their regulators. There are large variations between individual CYP450 isoforms in terms of their susceptibility to these mechanisms [35,36]. Overall, 57 CYP450 genes and 58 pseudogenes have been identified, 42 of which play a role in the metabolism of both exogenous xenobiotics and endogenous substances (e.g., steroids and prostaglandins), and 15 of which are involved in the metabolism of drugs in humans [35,36]. CYP450 genes are highly polymorphic and can exhibit clinically significant genetic polymorphisms. In general, CYP3A4/5, CYP2D6, CYP2C9, CYP2C19, CYP2A6, CYP2B6, and CYP2C8 are the most important and most studied metabolic enzymes. The variations in CYP450 genes—deletions, missense mutations, deleterious mutations (creating splicing defects or premature stop codons), and duplications—can result in abolished, reduced, normal, or enhanced enzyme activity [21,35,37,38].

17.3.1.1 CYP2D6

CYP2D6 is a member of the cytochrome P450 superfamily involved in metabolizing and eliminating many prescribed medications; it accounts for approximately 2% of total hepatic CYP450 content. The *CYP2D6* gene is highly polymorphic, with at least 100 genetic variants and 120 alleles identified. Additionally, its variants are the best characterized among all CYP450 variants, and the distributions of these alleles exhibit notable interethnic differences. (See Chapter 16.) Approximately 7–10% of Caucasians and 1% of Chinese, Japanese, and Koreans are PMs of CYP2D6 [34,39,40].

In Caucasians, *CYP2D6**3, *4, and *5 produce inactive enzymes or no protein products and are the variants most commonly implicated in the PM phenotype. *CYP2D6**4 is the most common variant allele in Caucasians (allele frequency ~21%), but it is virtually absent in Chinese, although overall CYP2D6 activity is lower in Chinese than in Caucasians as a result of the high allele frequency of *CYP2D6**10 (~50%), which is largely absent in Caucasians. Gene duplication occurs in ~1–7% of Caucasians and 29% of black Ethiopians; also, it is predictive of an UM phenotype [34]. This variant produces an unstable enzyme with reduced (but not absent) ability to metabolize substrate drugs.

CYP2D6 is responsible for the metabolism of almost 20–30% of drugs and is the most widely studied enzyme in relation to polymorphisms. Examples include tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), antiarrhythmics, beta-blockers, neuroleptics, opioid analgesics, antiemetics, and anticancer drugs. CYP2D6 is not inducible, and therefore variations in the enzyme expression and activity are largely attributable to genetic polymorphisms [21,41]. Powerful CYP2D6 inhibitors have been shown to significantly decrease EM metabolic capacity; therefore, EM subjects may seem to be PMs during the coexisting administration of potent inhibitors (e.g., fluoxetine and paroxetine) [39].

Recently, ADRs have been reported in UMs, mainly of a 10- to 30-fold increase in drug metabolite concentrations. For example, codeine is converted through CYP2D6 to morphine, which is more pharmacologically active. UMs receiving standard doses of codeine have been reported to display symptoms of narcotic overdose significantly related to higher morphine concentrations [39,42]. Perhexiline is an antianginal drug that is almost entirely metabolized by CYP2D6 to hydroxyperhexiline (inactive). PMs have trough concentrations up to 6-fold higher than EMs after a single dose, with evidence of saturable metabolism. The major toxicity of perhexiline is hepatotoxicity and peripheral neuropathy, which are concentration-dependent. Therapeutic drug monitoring has assisted dosing, with a suggested range of 0.15–0.6 mg/l, supported by both concentration-dependent efficacy and toxicity [43]. This supports a case for prospective genotyping.

In most individuals, only a small fraction (~10%) of codeine is metabolized to morphine via CYP2D6, with most of that fraction glucuronidated to codeine-6-glucuronide and the remainder metabolized by CYP3A4 to norcodeine. The AUC of codeine is similar in PMs and EMs, whereas morphine is virtually undetectable in PMs as well as EMs taking quinidine (phenocopying). Clinical studies in volunteers generally support the lack of analgesia in PMs, which is consistent with the belief that morphine is the key metabolite responsible for codeine's antinociceptive effects. Theoretically, UMs may convert codeine to morphine more rapidly, resulting in increased opioid effects for a given dose. However, studies to date have been with volunteers and not the target population.

Overall there is a strong argument for a gene–concentration effect resulting from the failure of prodrug conversion to morphine in PMs and phenocopied EMs. As far as the gene–effect relationship is concerned, there seems to be a predictable failure of analgesia in healthy volunteers but a less clear relationship with adverse effects. Although nonresponse to codeine may be explained by PM status, it also may be due to other factors, including phenocopying by a CYP2D6 inhibitor such as paroxetine [34].

The beta-1-selective metoprolol appears to have both consistent gene–concentration and gene–effect relationships in healthy volunteers, suggesting that dose reduction to ~25% should occur in PMs or those phenocopied by other drugs [34]. Metoprolol is administered as a racemate, with S-metoprolol thought to produce most of the β-blockade. The main metabolite, O-desmethylmetoprolol (essentially inactive), accounts for approximately two-thirds of the metabolism and occurs via various pathways, including CYP2D6 (mainly R-metoprolol); another pathway, to α-hydroxymetoprolol, accounts for ~10% of the dose in EMs and seems to be under CYP2D6 control because very little is produced in PMs. AUCs of metoprolol are 4- to 6-fold higher in PMs than in EMs after one dose and 3- to 4-fold higher after repeated dosing. UMs achieve metoprolol concentrations that are half those observed in EMs. The strong CYP2D6 inhibitor, paroxetine, increases the mean AUCs of S- and R-metoprolol by 5- and 8-fold, respectively.

Enhanced or prolonged β-blockade has been observed in both PMs and EMs receiving CYP2D6 inhibitors [44,45]. Three recent prospective studies failed to show a relationship between CYP2D6 and adverse effects with metoprolol [46–48]. The high therapeutic index of the drug and the fact that the effects of excessive β-blockade are usually easy to detect clinically (e.g., bradycardia) lessen the need for genotype testing. The long history of metoprolol use without genotyping or phenotyping suggests that these tests are unlikely to happen in practice.

17.3.1.2 CYP2C9

CYP2C9 is the most abundant of the CYP2C enzymes and accounts for about 30% of total hepatic CYPs. It plays an important role in the metabolism of about 10% of the drugs available on the market, including nonsteroidal anti-inflammatories (e.g., ibuprofen), antiepileptics (e.g., phenytoin), oral anticoagulants (e.g., warfarin), and antihypertensives (e.g., losartan). The human *CYP2C9* and *CYP2C19* genes are highly homologous at the nucleotide level [39,49], and more than 30 variants of *CYP2C9* have been identified. Generally, *CYP2C9* polymorphisms encode proteins with a loss of catalytic function, with the extent this reduction often being substrate-dependent.

Many variants have been associated with reduced enzyme activity (see http://www.cypalleles.ki.se), with *CYP2C9**3 and, to a lesser extent, *2 having the most clinical relevance. *In vitro* studies show that **3* is associated with a lower intrinsic clearance of substrate drugs than is *2. The effects of *CYP2C9**2 are more substrate specific (e.g., warfarin and phenytoin), whereas *CYP2C9**3 displays reduced catalytic activity toward the majority of

CYP2C9 substrates. The clinical importance of *CYP2C9* polymorphisms is demonstrated by the dose adjustment of an oral anticoagulant, warfarin, based on the *CYP2C9* genotype[4,39,49,50].

At least one *CYP2C9**2 or *3 allele is carried by ~20% and 12% of Caucasians, respectively, with ~2.5% being homozygotes for *2 or *3, or for compound heterozygotes for both alleles. The remaining two-thirds of the Caucasian population are wild types and have normal enzyme activity. The small proportion of individuals (~0.4% of Caucasians) homozygous for *CYP2C9**3 have the lowest ability to metabolize substrate drugs. The *CYP2C9**2/*2 and *2/*3 genotypes may also cause important reductions in the metabolism of some drugs (e.g., phenytoin). *CYP2C9**2 and *3 are rare in African American and Asian populations, with the wild type making up more than 95% of these populations [51].

The three oral coumarin anticoagulants—warfarin, acenocoumarol, and phenprocoumon—exist as S- and R-enantiomers. The S-enantiomers are CYP2C9 substrates and are responsible for most of the effects of warfarin and phenoprocoumon. In contrast, although S- and R-acenocoumarol have comparable activities, rapid elimination of the S-enantiomer means that R-acenocoumarol produces most of the anticoagulant effect. All three oral anticoagulants have low therapeutic indices, and the dose required to produce a target prothrombin time is largely unpredictable [34] (see Chapter 24). CYP2C9 is important for the metabolism of this class, with *CYP2C9**3 (but not *CYP2C9**2) being clearly implicated in impaired clearance of tolbutamide, glyburide, and glimepiride [52–54].

Losartan is metabolized by CYP2C9 via an aldehyde intermediate (E-3179) to E-3174, the predominant active moiety. E-3174 is at least 10-fold more potent than losartan at the AT1 receptor. Furthermore, although only 14% of losartan is metabolized to E-3174, the AUC of the latter is 4-fold to 8-fold higher than that of the parent and is thought to be responsible for most of the activity [55]. This finding suggests that individuals with *CYP2C9* variants might exhibit a reduced losartan response. Only one of the three studies in healthy volunteers that included blood pressure assessments reported a significant influence of CYP2C9; they reported reduced response among those with the *1/*3 genotype [56–58]. Studies on the impact of genotype on AUC have been inconclusive, and it seems unlikely that *CYP2C9* variants significantly affect parent losartan concentrations since production of E-3174 constitutes a quantitatively minor route of elimination [56–59].

Phenytoin is a commonly used antiepileptic drug despite its complex nonlinear pharmacokinetics and low therapeutic index. It is primarily (80–90%) eliminated via 4′-hydroxylation to 5-(4p-hydroxyphenyl)-5-phenylhydantoin (HPPH), largely via CYP2C9, which preferentially produces the S-enantiomer of HPPH. The presence of at least one *CYP2C9**2 or *3 allele is associated with one-third lower mean dose requirements (199 versus 314 mg/day, respectively). Furthermore, a "gene-dose" effect seems to exist, with dose requirements of 314, 193, 202, 217, and 150 mg/day for the *CYP2C9**1/*1, *1/*2, *1/*3, *2/*2, and *2/*3 genotypes, respectively [60].

In a single-dose study in healthy volunteers 30% lower concentrations were seen in wild-type individuals compared with carriers of *CYP2C9**2 or *3 alleles. *CYP2C9**2 and *3 were suggested as accounting for 31% of the variation in phenytoin concentrations taken 12 h after a single 300 mg dose [61]. As central nervous system toxicity (e.g., ataxia and nystagmus) is closely related to concentration, it is likely that individuals with *CYP2C9* variants are predisposed to these effects. There is some evidence for an association between *CYP2C9**1 and *3 genotype and cutaneous reactions [62]. A reasonable case for genotyping in relation to phenytoin to guide the initial choice of a maintenance dose can be made on the basis of a strong gene-(dose) concentration effect, a moderate gene-effect relationship, a strong concentration-effect relationship for both desired and adverse effects, and a low therapeutic index. Points against genotyping include the fact that an alternative pathway (CYP2C19) exists for phenytoin metabolism. Therapeutic drug monitoring continues to be necessary, and clinicians have long experience with phenytoin.

17.3.1.3 CYP2C19

CYP2C19 accounts for about 3% of total hepatic CYPs. The ability of individuals to metabolize S-mephenytoin has enabled them to be classified as PMs or EMs. PM phenotypes for CYP2C19 are common (20%) among Asians and rare (3–5%) in European-derived populations. CYP2C19 catalyzes the metabolism of several drugs, including proton pump inhibitors (PPIs) (e.g., omeprazole, lansoprazole, pantoprazole), antidepressants (e.g., citalopram and amitriptyline), antiplatelet drugs (e.g., clopidogrel), antifungals (e.g., voriconazole), and anticancer compounds (e.g., cyclophosphamide). Seven variants (*2–*8) in the *CYP2C19* gene have now been associated with reduced enzyme activity *in vivo*, largely due to production of inactive enzyme protein.

A novel *CYP2C19* variant (*CYP2C19**17) that may produce an ultrarapid metabolizer phenotype was recently identified [63]. A splice site mutation, *CYP2C19**2 (rs4244285, 19154G >A), and a premature stop codon, *CYP2C19**3 (rs4986893, 17948G >A) represent the two most predominant null alleles [4,39,64]. Genotyping for *CYP2C19**2 and *3 identifies most PMs in African American and Chinese populations, while genotyping for *CYP2C19**2 identifies 70–85% of variant reduced-activity alleles and *CYP2C19**2–*8 identifies more than 99% of PMs [65].

CYP2C19 plays an important role in proton-pump inhibitor (PPI) therapy for peptic ulcers and gastroesophageal reflux disease. In EMs, it is responsible for >80% of the metabolism of omeprazole, lansoprazole, and pantoprazole [66], the remainder with CYP3A4 [39,64]. The metabolites produced are inactive. A fourth PPI, rabeprazole, may be less reliant on CYP2C19 as it undergoes nonenzymatic conversion to rabeprazole thioether. S-Omeprazole (esomeprazole) was recently marketed as an individual entity to exploit its reduced variation in *CYP2C19* genotype pharmacokinetics compared with the racemate or with R-omeprazole [67].

The AUCs of both omeprazole and lansoprazole are 4- to 15-fold higher in PMs than in homozygous EMs; with multiple dosing, the increase in AUC of omeprazole (but not of lansoprazole or pantoprazole) decreases to ~2-fold in EMs because of inhibition of its own metabolism by CYP2C19 [68]. This does not occur in PMs who lack a functioning CYP2C19 enzyme to inhibit. The AUCs of rabeprazole are also increased but less markedly in CYP2C19 deficiency. Individuals with CYP2C19 deficiency have superior acid suppression with conventional doses of omeprazole and lansoprazole [69], and increasing the lansoprazole dose from 30 mg once daily to four times daily in homozygous EMs leads to an increase in mean 24-h intragastric pH from 4.5 to 7.0 [70].

Overall, omeprazole- and lansoprazole-based regimens produce lower eradication rates in homozygous EMs than in heterozygous EMs or PMs [71]. If patients are confirmed as being PMs, dual therapy with PPI and amoxicillin may be appropriate, as the eradication rate is likely to be high (>90%) [72]. The PPIs are an exceptionally well-tolerated class of drugs, and there seems to be no clear evidence of increased toxicity in PMs despite a markedly elevated AUC. However, individuals with a CYP2C19 deficiency may be predisposed to vitamin B12 deficiency during long-term use of this class [73].

17.3.1.4 CYP2A6

CYP2A6 is a member of the cytochrome P450 superfamily and is expressed predominantly in hepatic cells, with some expression in specialized extrahepatic cell types. Compared with CYP2D6 and CYP3A4, relatively few clinically used drugs are metabolized to a significant point by CYP2A6. Its substrates include coumarin, halothane, methoxyflurane, valproic acid, disulfiram, and losigamone [74]. A number of significant variations in CYP2A6 have been identified, including *CYP2A6**2 (rs1801272, 479T >A), *CYP2A6**4 (gene deletion), *CYP2A6**5 (rs5031017, 1436G >T), and *CYP2A6**20 (rs28399444, frame shift). These polymorphisms are associated with abolished enzyme activity and have different allele frequencies among ethnic groups. The prevalence of CYP2A6 PMs in the Caucasian population is ≤1% [39].

A deletion of the *CYP2A6* gene is common in the Asian population and accounts for significant differences in PMs compared with the Caucasian population. Since CYP2A6 is the high-affinity metabolizer of both nicotine and its oxidized metabolite, cotinine, *CYP2A6* variants have mainly been studied for treating tobacco abuse. Studies have revealed that the kinetics of nicotine metabolism are different in individuals carrying the variant *CYP2A6* alleles. For example, in three studies, smokers who carried the *CYP2A6* variants smoked fewer cigarettes and were more likely to quit smoking. These results reflect the possibility of increased nicotine concentrations and, subsequently, increased nicotine tolerance and ADRs from nicotine, especially in CYP2A6 PMs [39,74,75].

17.3.1.5 CYP2B6

CYP2B6 accounts for 6–10% of the total CYP contents in the liver, with a substantial (>100-fold) variation in expression between individuals [76]; it is involved in the metabolism of an increasing number of clinically important drugs (~8% of those on the market) [39,77], including bupropion, cyclophosphamide, efavirenz, and methadone. It also metabolizes some procarcinogens (e.g., 6-aminochrysene) and drugs of abuse (e.g., N-methyl-3,4-methylenedioxyamphetamine, "ecstasy"). CYP2B6 is subject to inhibition and induction by drugs such as clopidogrel and phenobarbital respectively [78,79]. A number of *CYP2B6* variants have been identified. *CYP2B6**6 (rs3745274, 516G >T and rs2279343, 785A >G) is the most common polymorphism. It commonly occurs in Caucasians and Asians, while *CYP2B6**16 (rs2279343, 785A >G) and *CYP2B6**18 (rs28399499, 21011T >C) are common in Africans [39].

CYP2B6 is the main catalyst of efavirenz metabolism (to its inactive 8-OH metabolite); therefore, its polymorphisms may have major implications for the PKs and toxicity of this drug, which at present is recommended as an option in first-line combination therapy for HIV infections [77]. Individuals homozygous for the 516T variant or the *CYP2B6**6 allele (516G >T and 785A >G) may have two to threefold higher efavirenz concentrations and may be predisposed to side effects. Studies have shown that when the efavirenz dose is decreased, the plasma concentrations of the drug decreases proportionally. It is reported that patients who were *6/*6 homozygous and *6/*26 and *1/*26 heterozygous had lower plasma concentrations of efavirenz and less frequent CNS effects when the dose was decreased [39,80].

17.3.1.6 CYP2C8

CYP2C8 accounts for approximately 7% of total hepatic content and plays a vital role in the metabolism of pioglitazone, amiodarone, paclitaxel, chloroquine, verapamil, and ibuprofen. It also plays a secondary role in the metabolism of fluvastatin, amitriptyline, diclofenac, omeprazole, and carbamazepine. The metabolism of paclitaxel to 6α-hydroxypaclitaxel, which is essentially inactive, has been used as an index of CYP2C8 activity *in vitro* [81]. The most common *CYP2C8* variants are *CYP2C8**2 (rs11572103, 11054A >T), *CYP2C8**3 (rs11572080, 2130G >A and rs10509681, 30411A >G), and *CYP2C8**4 (I264M substitution); they lead to decreased enzyme activity [21,39,82]. CYP2C8 is primarily responsible for the hydroxylation of R-ibuprofen; CYP2C9, for S-ibuprofen. The mean AUC after a single dose of 400 mg of racemic ibuprofen was reported to be 2.2- and 8.7-fold higher in individuals with the *CYP2C8**1/*3 or *3/*3 versus *1/*1 genotype [83].

*CYP2C9**2 has been associated with altered ibuprofen pharmacokinetics only when it is coinherited with *CYP2C8**3 (linkage disequilibrium) [83]. Several studies suggest that reduced paclitaxel metabolism may occur with the *CYP2C8**2 and *3 alleles, with the latter producing the greatest reduction [84]. *In vitro* data suggest that CYP2C8 and CYP3A4 are responsible for inactivating repaglinide, a nonsulfonylurea insulin secretagogue. CYP3A4 inhibitors such as ketoconazole and clarithromycin increase repaglinide concentrations by small amounts (15% and 40%, respectively) compared with a 5.5- to 15.5-fold increase with the CYP2C8 inhibitor gemfibrozil [85].

*CYP2C8**2 is more common in Africans, while *CYP2C8**3 and *4 are common in Caucasians. Both CYP2C8 and CYP2C9 play an important role in ibuprofen metabolism, and it has been found that CYP2C8 plays a key role in the hydroxylation of the (R)-enantiomer. For this reason, ibuprofen disposition has been used as a guide for CYP2C8 activity. When the effects of the different genotypes on ibuprofen PKs were investigated, *CYP2C8* polymorphisms were found to be common [82,86].

Studies have shown that the presence of the *CYP2C8**3 allele causes a significant effect on the disposition of ibuprofen, which suggests that a considerable proportion of Caucasian subjects may show alterations in the disposition of drugs that are CYP2C8 substrates. Moreover, in one study *CYP2C8**3 carriers who received R-ibuprofen had lower ibuprofen CLs; the *CYP2C8**3 heterozygotes who were treated with the antidiabetic repaglinide had a higher metabolism of the drug when compared to *CYP2C8**1 and *4 carriers [39,82,86].

17.3.1.7 CYP3A4/5

The CYP3A locus comprises four genes that code for the functional enzymes: CYP3A4, CYP3A5, CYP3A7, and CYP3A43. Of these CYP3A7 is primarily fetal and CYP3A43 is minimally expressed and has low functional activity. CYP3A4/5 is responsible for metabolizing the largest number of prescribed drugs (more than 50%), including cyclosporin, indinavir, nifedipine and simvastatin. These genes are often considered collectively as "CYP3A" because of their promiscuous substrate specificity and the difficulty discerning the relative role of each isoform in drug metabolism [34]. The overall activity of CYP3A is unimodally distributed, exhibits wide interindividual variability (>10-fold), and is highly susceptible to the effects of enzyme inhibitors and inducers [87].

More than 20 variants in the coding region of CYP3A4 have been described [39], and a number of them have altered enzyme activities, ranging from a modest to a significant loss in catalytic efficiency; however, their clinical significance is uncertain. *CYP3A4**2 (rs55785340, 664T >C) and *CYP3A4**7 (rs56324128,167G >A) have higher frequencies in Caucasian populations, whereas *CYP3A4**16 (rs12721627, 554C >G) and *CYP3A4**18 (rs28371759, 878T >C) have higher frequencies in Asian populations [4].

A single point mutation (6986A >G) in intron 3 of CYP3A5 (designated CYP3A5*3) produces a truncated and nonfunctional protein. In contrast to the unimodal distribution of CYP3A taken as a whole, CYP3A5 exhibits a bimodal distribution that can be predicted by the presence or absence of this allele. Individuals homozygous for CYP3A5*3 produce little CYP3A5 enzyme ("low expressors"), whereas the remainder have at least one wild-type (CYP3A5*1) allele and express a large amount of CYP3A5 ("high expressors").

The PKs of the immunosuppressive agent tacrolimus are mainly dependent on the *CYP3A5* genotype, and in terms of the dose required to reach target trough blood concentrations (C0). Tacrolimus C0 and its dose requirements are related to *CYP3A5* polymorphisms; for example, individuals who carry at least one *CYP3A5**1 allele have a functional CYP3A5 and consequently need a higher dose of tacrolimus to reach the targeted blood concentration. CYP3A5 expressors experience a delay in reaching target concentrations [4,88]. It is estimated that 10–20% of Caucasians, 40–50% of East Asians, 60–70% of Hispanics, and >80% of African Americans are high expressors of CYP3A5 [89].

17.3.2 Non-CYP450 Enzymes

Here we discuss the variations in the non-CYP450 enzymes: UGT, TPMT, NAT, and GST.

17.3.2.1 UDP Glucuronosyltransferases

UDP Glucuronosyltransferases (UGTs) are expressed in a tissue-specific and frequently inducible way in most human tissues; their highest concentration is found in the GI tract and liver. UGTs contribute to about 35% of phase II drug metabolism and are involved in the glucuronidation of many endogenous compounds and xenobiotics [39]. Nineteen human genes are encoded by UGT proteins: 9 by *UGT1* and 10 by *UGT2*. While both types are involved in the process of drug metabolism, UGT2 seems to have greater specificity for the glucuronidation of endogenous substances (e.g., steroids). *UGT1A1* expression plays a vital role in drug metabolism because the glucuronidation of bilirubin by UGT1A1 is the rate-limiting step that assures effective bilirubin conjugation levels. This rate can be influenced by both genetic variation and drug treatments. If a drug undergoes selective metabolism by UGT1A1, competition for its metabolism with bilirubin, glucuronidation occurs, resulting in marked hyperbilirubinemia in addition to decreased clearance of the metabolized drug [4,20,90].

UGT1A1 recently gained recognition as the first pharmacogenetic test to achieve FDA approval for use in conjunction with a specific drug (irinotecan). Irinotecan is a prodrug that is metabolized by carboxylesterases to the active topoisomerase inhibitor 7-ethyl-10-hydroxycamptothecin (SN-38) and by CYP3A4 to inactive metabolites. Thereafter, SN-38 is glucuronidated by UGT1A1, with the resultant SN-38 glucuronide excreted into the intestine via bile [91].

The activity of UGT1A1 varies widely, with an *in vitro* study demonstrating a 17-fold variation in SN-38 glucuronidation. *UGT1A1**28 is the variant most frequently implicated in defective SN-38 glucuronidation and involves an extra thymine-adenine (TA) repeat in the TATA section of the *UGT1A1* promoter (i.e., $(TA)_7TAA$ instead of $(TA)_6TAA$ in the wild type). It is also the primary cause of Gilbert's syndrome [92]. This variant occurs commonly, with the homozygous genotype found in 5–15% of Europeans, 10–25% of Africans and South Asians, and 1–5% of Southeast Asians and Pacific Islanders. There is an increased risk of severe neutropenia and diarrhea with irinotecan in homozygotes for *UGT1A1**28 compared with homozygotes for *UGT1A1**1 [93].

Gilbert's syndrome can be caused by a number of genetic changes, and patients with it may experience adverse drug reactions (ADRs) because of reduced capacity to metabolize drugs by UGT1A1. *UGT1A1**37 has an 8-TA insertion in the promoter and results in more decreased promoter activity than that of the *UGT1A1**28 allele. *UGT1A1**36 (rs8175347) has only a 5-TA insertion in the promoter and is associated with increased enzyme activity and a decreased risk of neonatal hyperbilirubinemia [20,90].

17.3.2.2 Thiopurine S-methyltransferase

Thiopurine S-methyltransferase (TPMT) catalyzes the S-methylation of 6-mercaptopurine (6-MP), azathioprine (AZA), and thioguanine to inactivate these drugs, which are used for treating leukemia and autoimmune diseases. It is a cytosolic enzyme found in many tissues, with activity most commonly determined in red blood cells. In Caucasians, a trimodal distribution exists, with 0.3–0.6% having low or undetectable activity, 10% having intermediate activity, and the remaining 90% having high (normal) activity [94]. The *TPMT* gene exhibits significant genetic polymorphisms across all of the ethnic groups studied, and TMPT activity is highly variable, as well as polymorphic, in all large populations evaluated up to the present time. About 90% of Caucasians inherit high enzyme activity, 10% inherit intermediate activity (heterozygous), and 0.3% inherit low or no activity. A number of clinically significant SNPs have been identified for *TMPT* that can alter its activity, and since methylation is involved in both the activation and the metabolism of mercaptopurine, altered enzyme activity affects the concentration of both active and toxic metabolites [4,21,39].

The genetic polymorphisms of *TMPT* have the strongest case for prospective pharmacogenetic testing. Generally, thiopurine agents have a narrow therapeutic index, with life-threatening myelosuppression being a major concern. Patients with polymorphic TMPT frequently require a significant dose reduction in order to prevent toxicity. More than 20 variants of the *TPMT* gene have been identified; however, the most studied are *TPMT**2, *3A, *3B, and *3C, which are responsible for most cases of TPMT deficiency. These three variants account for 80–95% of intermediate and poor metabolizers [4,21,39]. *3A is the most common variant in Caucasians; *3C is the most common in Africans and Southeast Asians. Homozygotes for a variant allele (e.g., *TPMT**3A/*3A) have negligible TPMT activity, whereas heterozygotes (e.g., *TPMT**1/*3A—intermediate activity) have an average activity that is approximately half that observed in homozygotes for wild-type alleles (*TPMT**1/*1, normal/high activity). Genotyping is reasonably accurate in predicting TPMT phenotype, which is defined as low, intermediate, or normal/high TPMT activity [95].

The therapeutic niche of TPMT testing relates to its ability to identify prospectively the small proportion of patients (0.3–0.6%) with enzyme deficiency who will almost certainly develop life-threatening myelosuppression if standard doses are used. Although it is clear that TPMT deficiency (particularly complete deficiency) predisposes to myelotoxicity, approximately 75% of cases of bone marrow depression occur in those without mutations (i.e., presumed normal enzyme activity) [96]. This indicates that TPMT metabolizer status is a useful adjunct to (but not replacement for) regular blood-count monitoring. The clinical usefulness of prospective determination of TPMT metabolizer status is supported by pharmacoeconomic studies [97].

17.3.2.3 Dihydropyrimidine Dehydrogenase

Dihydropyrimidine dehydrogenase (DPD), an enzyme encoded by the DPYD gene, metabolizes two endogenous pyrimidines—thymine and uracil—and facilitates the metabolism of the pyrimidine analog 5-fluorouracil (5-FU). DPD activity in peripheral blood mononuclear (PBM) cells has been used as a surrogate for total body DPD activity and varies up to 20-fold. DPD activity is usually described as normally distributed, perhaps reflecting the absence of cases of absolute deficiency in the studies [98]. DPD polymorphisms result in DPD-deficient phenotypes with a total frequency of about 3–5%. DPD variants, such as *DPYD**13 (rs55886062, 1679T >G), *DPYD**9A (rs1801265, 85T >C), *DPYD**2A (rs3918290, IVS14+1G >A), and 2846A >T (rs67376798, D949V), are among the identified SNPs associated with grade 3 and grade 4 toxicities in 5-FU–treated patients. For example, *DPYD**2A homozygous patients have a complete absence of normal DPD activity, whereas heterozygous carriers have a 50% absence of the enzyme activity, resulting in 5-FU accumulation and significant life-threatening 5-FU–related toxicities [39].

Moreover, *DPYD**9A is a common missense mutation with a C29R substitution; however, its association with reduced DPD activity is still debatable. For example, two different studies reported that cancer patients who were *DPYD**9A heterozygous had severe 5-FU toxicity in. Together, DPYD*2A and *DPYD**9A polymorphisms have a high concordance with 5-FU toxicity but a low concordance with enzyme activity. Determination of PBM cell DPD activity (i.e., phenotype) may identify up to 60% of patients who may develop severe toxicity, whereas screening solely for the *DPYD**2A allele (genotype) identifies approximately 25% of these patients. Identification of a patient with absolute deficiency would allow selection of alternative chemotherapy, whereas those with partial deficiency can be treated with a lower dose of 5-FU. The increasing availability of DPD inhibitors (eniluracil) may make assessment of metabolizer status redundant.

17.3.2.4 N-acetyltransferases

Human N-acetyltransferases (NATs) catalyze the acetylation of aromatic amines and hydrazines. There are two functional NAT genes in humans, *NAT-1* and *NAT-2*, which carry functional polymorphisms that influence enzyme activity [4]. More than 25 allelic variants of these functional genes have been identified. Based on the level of NAT activity, patients can be classified into two phenotypes: fast acetylator (FA—wild-type NAT acetylation activity) and slow acetylator (SA—reduced NAT enzyme activity). NAT-1 activity is usually constant, whereas NAT-2 polymorphisms result in individual differences in the rate at which drugs are acetylated. While several mutations have been identified in the *NAT1* and *NAT2* genes, the frequency of the slow acetylation patterns is attributed mostly to polymorphisms in the *NAT2* gene [4,20,21].

Altogether, *NAT2* polymorphisms result in more than 10 *NAT2* alleles, and the variant alleles that account for the majority of SA phenotypes include *NAT2**5 (rs1801280, 341T >C), which results in an I114T substitution; *NAT2**6 (rs1799930, 590G >A), which causes a R197Q substitution; and *NAT2**7 (rs1799931, 857G >A), which corresponds to a G186E substitution [39]. A number of compounds have been used as a probe for NAT2, and a good genotype–phenotype correlation is generally observed (>90%) with caffeine as a probe [99].

Slow acetylators are found in approximately 50% of European- and African-derived populations, but they are less common in Asians. Individuals phenotyped as slow acetylators are likely to have two slow activity alleles, whereas those phenotyped as fast acetylators can have one or two high-activity alleles (most likely *NAT2**4, which is considered to be the wild type). In Caucasians, most of the fast acetylators are heterozygotes for slow and fast alleles, whereas individuals homozygous for fast alleles (e.g., *NAT2**4/*4) comprise ~5% of the population [99].

In contrast, ~30% of Chinese individuals are homozygous for rapid alleles, 45% are heterozygous, and 25% are homozygous for slow alleles [100]. *NAT2* polymorphisms and their association with the slow acetylation of isoniazid (an antituberculosis drug) were one of the first fully characterized genotypes shown to influence drug metabolism, which links the pharmacogenetic (PG) phenotype to a genetic polymorphism [20] (see Chapter 36). Since NAT1 and NAT2 catalyze the bioactivation (via O-acetylation) of aromatic and heterocyclic amine carcinogens, genetic variations in the *NAT1/2* genes may alter the cancer risk associated with exposure to these carcinogens. *NAT2* polymorphisms are related to individual susceptibility to particular cancers caused by industrial chemicals (e.g., α- and β-naphthylamine); for example, individuals with poor acetylator phenotypes have increased risks of lung, bladder, and gastric cancers if exposed to carcinogenic arylamines for a long period of time [4,21].

17.3.2.5 Glutathione S-transferases

The superfamily of human glutathione S-transferases (GSTs) facilitates the conjugation of glutathione (GSH) to different endogenous metabolites and xenobiotics. GSTs include 10 members, which are divided into 3 main groups: cytosolic/nuclear, mitochondrial, and microsomal. Cytosolic GSTs are also divided into 7 classes: alpha, mu, omega, pi, sigma, theta, and zeta, the most important of these being *GSTM1*, *GSTT1*, *GSTP1*, and *GSTA1*. In addition to their enzymatic function, GSTs also act as regulators of many physiological processes, including cell signaling and growth factors and DNA replication [21].

The PKs of many drugs can be affected by *GST* polymorphisms, and since they decrease the activity of metabolizing enzymes, biologically active parent drugs or metabolites can accumulate and reach toxic levels. A number of known *GST* variants are well characterized in their influence on drug disposition. Two polymorphisms of the *GSTP1* gene have been identified: 1404A >G SNP (rs947894), with an I105V substitution, and 2294 C >T SNP (rs1799811), with an A114V substitution [39].

17.3.3 Drug Transporters

The movement of drugs across the cell membrane is through a combination of both passive diffusion and active transport, facilitated by certain drug uptake and efflux molecules. Drug transporters are membrane proteins that exist at various endothelial and epithelial barriers, including the BBB, intestinal epithelial cells, hepatocytes, and renal tubular cells. These transporters can significantly affect drug disposition. For example, the influx of a drug from the blood to the liver, where it is subsequently metabolized and excreted, may increase the rate of elimination. These proteins and the genes that encode them are essential to drug uptake, bioavailability, targeting, efficacy, toxicity, and clearance. Genetic variation in the genes encoding these transporters can result in variable expression levels and transport efficiency, which can have an impact on drug pharmacokinetics and response to treatment.

More than 300 human genes code transporters or transporter-related proteins, most of which work on endogenous substrates, although some also transport xenobiotics. Drug transporters can generally be classified into two groups: the efflux adenosine triphosphate-binding cassette (ABC), known as the multidrug resistance (MDR) family of transporters, and the uptake solute carrier single-level cell (SLC) family of transporters. SLCs mediate passive movement of solutes down their electrochemical gradient, while ABCs are active pumps fueled by ATP [39,101].

17.3.3.1 ABC Transporters

There are a total of 49 members of the human ABC transporter family, and they are grouped into seven subclasses or families (ABCA through ABCG) [102]. These transporters generally counteract uptake through the intestinal wall, efflux substrates out of tissues into systemic circulation, and eventually mediate the clearance of drugs from the body. Of all ABC transporters, the best known are ABCB1 (P-glycoprotein, Pgp, or MDR1), ABCC1/2 (multidrug resistance–related proteins 1/2, MRP1/2), ABBC2 (multidrug resistance, MRP2) and ABCG2 (breast cancer resistance protein, BCR). ABCB1 and ABCG2 are the most characterized [103]. They are expressed in the enterocytes, colon, intestinal epithelium, canalicular plasma membrane of hepatocytes, proximal renal tubule, hematopoietic stem cells, blood–brain barrier, heart, nerves, testes, and placenta. In all of these tissues, except the blood–brain barrier, they mediate efflux substrates out and into systemic circulation. ABCB1 in the choroid plexus, transports molecules from circulation into cerebrospinal fluid.

It is believed that the evolutionary role of ABC transporters is to limit the penetration of toxic molecules into critical organs, thereby protecting blood–tissue barriers [104,105]. ABCC1 is expressed ubiquitously and is localized to the basolateral, rather than apical, membranes of epithelial cells. Because of its basolateral localization, ABCC1 pumps drugs into the body rather than into the bile, urine, or intestine. For this reason, it is thought to serve mainly as a protective barrier in tissue epithelial cells rather than as a classic drug efflux pump. ABCC2 is functionally similar to ABCB1 and is expressed on the apical domain of epithelial cells in liver, intestine, and kidney [104,105].

ABCB1

ABCB1/MDR1 was the first recognized and most extensively studied ABC transporter encoding a polypeptide (P-glycoprotein, or P-gp). P-gp has two halves, each containing six hydrophobic transmembrane domains and an ATP-binding domain. The expression of *ABCB1* on the apical surface of enterocytes and the canalicular part of the hepatocyte has been shown to influence intestinal drug absorption and limit oral bioavailability of a wide variety of structurally diverse drugs. Additionally, it facilitates hepatobiliary excretion and renal excretion, and protects the brain and fetus from xenobiotics. ABCB1 overexpression in cancer cells is involved in multidrug resistance to chemotherapeutic agents [21,106,107].

ABCB1s are responsible for amphipathic lipid-soluble drugs. They transport a broad spectrum of structurally and functionally different drugs, such as anticancer agents (e.g., anthracyclines), antibiotics (e.g., erythromycin), immunosuppressants (e.g., cyclosporine), cardiac drugs (e.g., digoxin), calcium channel antagonists (CCB) (e.g., diltiazem), and HIV protease inhibitors (e.g., ritonavir).

The most common SNPs are the synonymous 1236C >T (rs1128503) and 3435C >T (rs1045642), and the nonsynonymous 2677G >T (rs2032583) [21,106], all three of which have allele frequencies that vary in different ethnic populations, with a higher frequency among Caucasians and Asians. The 3435C >T SNP has strong linkage disequilibrium with other SNPs in the *ABCB1* gene, creating common haplotypes consisting of 3435C >T combined with 2677G >T and/or 1236C >T. In general, SNP association studies on bioavailability and efficacy are inconclusive [105]. 3435C >T SNP was first shown to be associated with reduced serum digoxin concentrations, whereas it was also associated with higher plasma digoxin levels. The association was stronger when the *ABCB1* 2677G >T/A and 3435C >T polymorphisms were evaluated together as a haplotype [108].

Many investigators have now found similar associations between these polymorphisms and plasma concentrations of several other drugs, although these observations have not been consistently confirmed. More recent evidence suggests that polymorphic ABCB1 expression influences not only plasma pharmacokinetics but also the degree to which drugs are able to penetrate into tissues that express *ABCB1*. In a study of chronic myeloid leukemia patients treated with imatinib, patients with the 1236C >T had higher imatinib plasma concentrations and also showed an improved therapy response, whereas the presence of the wild-type 2677G variant worsened clinical response [109]. In a stable recombinant cell model, the anticancer drugs doxorubicin HCl, daunorubicin HCl, vinblastine sulfate, vincristine sulfate, taxanes (paclitaxel), and epipodophyllotoxin (etoposide, VP-16) exhibited selectively reduced Pgp-mediated resistance in 561A carriers [110].

In general, there is an overlap in substrate specificity and tissue distribution for ABCB1 and CYP3A4/5. Some drugs are dual substrates for both ABCB1 and OATP transporters (e.g., digoxin, fexofenadine, atenolol). Cyclosporine is not only transported by ABCB1, but is also metabolized by CYP3A4; consequently, the possible ABCB1 effects can be influenced by the activity of OATP transporters or CYP3A4 [21,39]. These may explain the conflicting results obtained with ABCB1 studies.

ABCC1 and ABCC2

ABCC1 and ABCC2 have overlapping substrate specificities, such as many anticancer agents (e.g., vincristine, doxorubicin), HIV protease inhibitors (e.g., ritonavir, saquinavir), and antibiotics (e.g., difloxacin, grepafloxacin). Both ABCC1 and ABCC2 need co-transport of reduced glutathione (GSH) to transport some of their substrates [12,21,111,112].

ABCC1 is ubiquitously expressed, whereas ABCC2 is mostly expressed in hepatocytes, renal proximal tubule cells, the intestine, and the brain. Genetic variants in *ABCC1* are relatively rare, and around 16 SNPs in both of its noncoding and coding regions have been determined to cause amino acid changes [21,112]. However, none of them significantly influence the expression level, indicating that the amino acid exchanges do not substantially affect the synthesis or stability of the protein. Gly671Val (rs45511401) in *ABCC1* and a haplotype of *ABCC2* were found to cause anthracycline-induced cardiotoxicity, as a consequence of the higher concentration of the drug, among non-Hodgkin lymphoma patients treated with doxorubicin [21].

In general, the influence of ABCC2-medicated transport on the pharmacokinetics of drug substrates in humans is not fully understood. Tumor cells often show an inducible expression of *ABCC2*, which contributes to drug resistance. Because of the transport of bile acids and glutathione from the hepatocytes into the bile duct, ABCC2 plays a physiologically important role in forming bile flow and potentially in detoxification by delivering glutathione for conjugation of xenobiotics.

The polymorphism −24C >T in the 5′-UTR is in strong linkage disequilibrium with 3972C >T. Renal allograft transplant recipients harboring the −24T allele show a decreased oral clearance for the immunosuppressant mycophenolic acid (MPA), which is the active metabolite of mycophenolate mofetil. In consequence, these patients are more protected from a decrease in MPA exposure but with a higher association to mild liver dysfunction [113]. High-dose methotrexate treatment in pediatric ALL induced a twofold higher AUC and a ninefold higher risk of intensification of folinate rescue in female patients carrying the −24 variant allele [114]. In non-small-cell lung cancer patients, *ABCC2*−24TT and 3972TT genotypes were associated with higher response rates and longer progression-free survival, which was sustained in haplotype analysis.

This suggests a more effective exposure to irinotecan [115]. A missense SNP 1249G >A (Val417Ile) is located in the substrate-binding region of the first transmembrane domain and is associated with lower oral bioavailability and increased residual clearance after intravenous administration of the beta-blocker talinolol, which indicates higher intestinal transporter activity [116]. It has also been found to be correlated with renal proximal tubulopathy after treatment with the HIV protease inhibitor tenovir disoproxil fumarate, probably because of a toxic concentration of the drug in renal tubular cells after being actively secreted into them from the blood by ABCC2 [117]. The silent polymorphism 1446C >G is associated with higher ABCC2 mRNA expression in the liver and with a decreased AUC and peak concentration (C_{max}) of the cholesterol-lowering drug pravastatin [118].

ABCG2

ABCG2—also known as breast cancer resistance protein (BCRP) or mitoxantrone-resistant protein (MXR) or placenta-specific ATP binding cassette transporter (ABCP)—is an ABC half-transporter with six transmembrane domains and only one ATP-binding domain. Overall, it is expressed at various sites, including the liver, small intestine, colon, placenta, lung, kidney, adrenal and sweat glands, and central nervous system vasculature.

More than 80 polymorphisms in the *ABCG2* gene have been identified in different ethnic populations, with a higher frequency among Asians and Caucasians. A number of *ABCG2* SNPs have been found to influence the function and/or expression of the encoded protein. For example, *ABCG2* variant alleles alter drug exposure by reducing the biliary excretion of diflomotecan and rosuvastatin, causing variations in drug effects [4,119].

The nonsynonymous variant, 421C >A SNP (rs2231142), affects the PK of many drugs, including irinotecan, rosuvastatin, sulfasalazine, and topotecan. It has been reported that the 421A variant exhibits 1.3-fold decrease in ATPase activity compared to the wild type, with elevated bioavailability of diflomotecan and topotecan. The AUC of rosuvastatin following a single oral administration has been shown to be greater in 421C >A heterozygotes and homozygotes, but the heterozygotes did not show any difference in the PK profile of irinotecan and its active metabolite, SN-38 [119]. The AUC and peak concentration of rosuvastatin increased 2.4-fold in healthy individuals with the homozygous 421AA genotype compared to that in individuals with the 421CC genotype, but did not affect the elimination of $t_{1/2}$, which signifies that 421C >A affects the intestinal absorption of rosuvastatin [120].

17.3.3.2 SLC Transporters

The SLC family comprises 360 members, subdivided into 47 subfamilies, that encode membrane proteins identified as passive transporters, ion-coupled transporters, and exchangers. The better-known SLC transporters are the organic anion–transporting polypeptides (OATPs) and the organic cation transporters (OCT).

Organic Anion–Transporting Polypeptides

Organic anion–transporting polypeptides (OATPs) have 12 transmembrane domains, with a large, highly conserved extracellular loop between the 9th and 10th transmembrane domains. *N*-glycosylation sites in extracellular loops 2 and 5 are consistent among the various members of the OATP family [121]. OATPs mediate the sodium-independent transport of a wide range of amphipathic organic compounds, including steroid conjugates, anionic oligopepties, thyroid hormones, bile salts, xenobiotics, and pharmaceuticals. A total of 11 OATPs have been identified and classified into 6 families, and in humans OATP1A2, OATP1B1, OATP1B3 and OATP2B1 are the best characterized for their roles in drug PK [4,39,122].

OATP1A2s encoded by the *SLCO1A2* gene are mainly expressed on the luminal membrane of small intestinal enterocytes and at the BBB, and play a role in the intestinal absorption and brain penetration of their substrates. OATP1A2 substrates include rosuvastatin, methotrexate. and D-penicillamine. A number of nonsynonymous polymorphisms have been identified in the *SLCO1A2* gene, some of which exhibit diminished *in vitro* transport activity toward OATP1A2 substrates [21,122,123].

The *SLCO1B1* gene encodes OATP1B1, also known as OATP-C, and is mainly expressed on the basolateral membrane of hepatocytes in the human liver. It plays a role in the hepatic uptake of substrate drugs, including statins, D-penicillamine, and rifampin [21,39]. The primary role of OATP1B1 is believed to be removal of substrates from the blood into the liver for subsequent elimination. More than 40 nonsynonymous variants have been identified in the *SLCO1B1* gene, some of them being associated with decreased transport activity and whose allele frequencies vary markedly across different ethnic populations. Functionally impaired OATP1B1 SNPs may decrease the uptake of substrate drugs into the hepatocytes, resulting in decreased biliary excretion or hepatic metabolism, which is a consequence of increased systemic exposure [21,120,124]. OATP1B1 is one of the mechanisms underlying both drug–drug interactions, due to competition at the transporter, and pharmacokinetic variation, due to genetic polymorphisms in the gene encoding the OATP1B1 protein *SLCO1B1*.

The most commonly studied OATP1B1 variants are the 521T >C SNP (rs4149056) and the 388A >G SNP (rs2306283), which are in linkage disequilibrium and exist together in several haplotypes. The variant allele 521T >C is more common among Caucasians (8–20%) and Asians (9–16%) than Africans [39,107]. It has consistently been found to cause a functional decrease in OATP1B1 activity based on altered *in vitro* transport of a number of substrates, including estrone-3-sulphate, estradiol-17β-D-glucuronide, pravastatin, atorvastatin, cerivastatin, rifampicin, and SN-38. Generally, there is a variant-dependent change in pharmacokinetics such that individuals homozygous for the 521T >C variant (CC) have the highest plasma concentrations, which is in line with *in vitro* data suggesting that this variant leads to a decrease in the function of OATP1B1 [111,125].

A genome-wide association study (GWAS) of 85 patients with myopathy and 90 matched controls from Study of the Effectiveness of Additional Reductions in Cholesterol and Homocysteine (SEARCH) identified an association with rs4149056 in the SLCO1B1 gene [126]. Following the accumulation of evidence on the SLCO1B1 521T >C polymorphism, the FDA announced an update to its simvastatin product-label recommendations in 2011.

SLCO2B1 encodes OATP2B1, which is also known as OATP-B, and shows substrate selectivity similar to that of OATP1B1. OATP2B1 is expressed in the luminal membrane of small-intestinal enterocytes, and have a role in drug absorption/disposition [39,122]. A number of OATP2B1 SNPs have been identified, including 1457C >T (rs2306168), 601G >A (rs35199625), 935G >A (rs12422149), and 43C >T (rs56837383). Patients who received montelukast, a leukotriene receptor antagonist, and who carry the 935A variant allele of the 935G >A SNP were reported to show lower plasma concentration of the drug as well as lower pharmacological response [39,122,123].

OATP1B3 (encoded by SLCO1B3) and OATP2B1 are mainly expressed on the sinusoidal membrane of hepatocytes, and mediate the hepatic uptake of their substrate drugs. OATP1B3 substrates include, digoxin, rifampin, methotrexate, D penicillamine, and cyclosporine. According to currently published findings, OATP1B3 appears to be unique in transporting digoxin and possibly also the taxanes docetaxel and paclitaxel [127]. Polymorphisms in SLCO1B3 include 334T >G (rs4149117) and 699G >A (rs7311358), both of which occur at a high frequency in Caucasian populations. While OAT1B3 mediates the hepatic uptake of many drugs, the role of its polymorphisms in drug disposition and response is not fully understood [111].

Organic Cation Transporters

Organic cation transporters (OCTs) belong to the solute carrier SLC22A family, which facilitates the intracellular uptake of a broad range of structurally diverse, small organic cations. Three OCT isoforms have been identified in humans: OCT1, which is encoded by *SLC22A1*; OCT2, which is encoded by *SLC22A2*; and OCT3, which is encoded by *SLC22A3*. OCT1 is primarily expressed in the basolateral membrane of hepatocytes, whereas OCT2 is expressed in the basolateral membrane of kidney proximal tubules. OCT1 and OCT2 substrates include metformin, cisplatin, imatinib, procainamide, citalopram, cimetidine, and quinidine. OCT3 is expressed in various tissues, including the placenta, heart, liver, and skeletal muscle. Additionally, OCT expression has been detected in several cancer cell lines and tumor tissue samples [21,39,107].

The 1393G >A polymorphism in *SLC22A1* was found to reduce the localization of OCT1 to the surface of the basolateral membrane of hepatocytes. Other variants, including 41C >T, 566C >T, 1201G >A, and 1256delATG (a deletion variant) have all been associated with decreased metformin uptake activity; increased AUC and Cmax; and the significantly decreased ability of metformin to lower glucose levels [111,128].

While several SNPs have been identified for the *SLC22A2* gene, the most important is the 808G >T SNP (rs316019). Since metformin's active renal secretion is through OCT2, any functional defect in OCT2 transport results in decreasing the drug's renal clearance. Homozygotes of low activity (808G >T SNP) have lower renal clearance and higher plasma concentrations of metformin compared to homozygous carriers of wild-type 270A [39,129]. Additionally, homozygous and heterozygous carriers of various haplotypes of low-activity alleles of some OCT1 variants—R61C (rs12208357), G401S (rs34130495), M420del (rs35191146), and G465R (rs34059508) among them—have shown significantly higher metformin renal clearance (20–30%).

The clinical use of cisplatin is related to dose-limiting nephrotoxicity, which occurs in one-third of patients regardless of intensive prophylactic measures. OCT2 has been involved in the cellular uptake of cisplatin, but its role in cisplatin-induced nephrotoxicity is not fully understood. Moreover, the nonsynonymous SNP 808G >T has been associated with reduced cisplatin-induced nephrotoxicity in patients. These results indicate the critical importance of OCT2 in PK and related cisplatin renal toxicity [39,129,130].

Previous studies showed that homozygous carriers of the low-activity OCT2 variant 270S have a significantly lower renal clearance and a higher plasma concentration of metformin than do homozygous carriers of the active variant 270A [21,129]. Additionally, homozygous and heterozygous carriers of various haplotypes of low-activity alleles of some OCT1 variants—including R61C (rs12208357), G401S (rs34130495), M420del (rs35191146), and G465R (rs34059508)—have shown significantly higher renal clearance of metformin PK (20–30%). In addition, low-function OCT1 variants (R61C, G401S, M420del, and G465R) have been associated with a significantly decreased glucose-lowering metformin response in healthy volunteers, probably by reducing metformin metabolism in hepatocytes—the major target sites of metformin's action. For OCT3, several synonymous SNPs have been identified in *SLC22A3*; however, their functional consequence has not been fully clarified and needs further study [21,39].

Organic Anion Transporters

Organic anion transporters (OATs) belong to the SLC22A family of solute-carriers, which facilitate the cellular uptake of a wide range of structurally diverse small hydrophilic organic anions. Several clinically important anionic drugs are OAT substrates, such as β-lactam antibiotics, diuretics, and nonsteroidal anti-inflammatories (NSAIDs). There are at least six OAT members (OAT1–6) [21], and four SLC22A genes that have been identified for encoding OATS: SLC22A6, which encodes OAT1; SLC22A7, which encodes OAT2; SLC22A8, which encodes OAT3; and SLC22A11, which encodes OAT4. In terms of tissue location, OAT1, OAT2, and OAT3 are expressed (mostly) in the basolateral membrane of the renal proximal tubules, mediating the uptake of drug substrates from the blood into the proximal tubule cells; OAT4, in contrast, is located at the apical side of the renal proximal tubule, functioning in the secretion of drug substrates into urine [21,107]. OAT1, OAT2, and OAT3 are responsible for the uptake of drugs into the tubular cells, and OAT4 mediates their secretion into the renal tubule [19,39]. Additionally, OAT1 is an example of transporter-related toxicity. Different studies have shown that OAT1substrates, such as cephaloridine and ß-lactam antibiotics, sometimes cause nephrotoxicity. OCT1 transports a number of drugs, such as metformin, which act partly through intracellular effects in hepatocytes [19].

Genetic variations in genes encoding OATs can contribute to interindividual variability in the renal clearance of many drug substrates. To date, a number of polymorphisms have been identified in the coding region and 5′ regulatory region of the *SLC22A6*, *SLC22A7*, *SLC22A8*, and *SLC22A11* gene variants, and some of them have caused changes in the transport activity of their encoded proteins. While different polymorphisms have been reported for genes encoding OAT—mainly SLC22A8 (encoding OAT3)—their allele frequency is $\leq 1\%$, and their functional significance has not been fully explained [21,39].

17.4 CONCLUSIONS

This chapter presented a broad outline of genetic variation affecting drug pharmacokinetics and consequently drug efficacy and toxicity that highlights the potential of pharmacogenomics to facilitate improved and more effective therapy. Important genetic associations that have been identified between variant genotypes and drug response phenotypes have prompted the FDA to revise labels for certain drugs to include relevant pharmacogenetic information and recommendations. For successful clinical implementation, there must be parallel development in genomic discovery and collaborative partnerships among stakeholders.

Chapter 18

Pharmacodynamic Pharmacogenomics

Linsay McCallum, Stefanie Lip, and Sandosh Padmanabhan
BHF Glasgow Cardiovascular Research Centre, Institute of Cardiovascular and Medical Sciences, University of Glasgow, UK

Chapter Outline

18.1 Overview 365
18.2 Basic Pharmacodynamics 365
  18.2.1 Historical Aspects 365
  18.2.2 Basic Principles 366
  18.2.3 Receptors 366
  18.2.4 Measurement of Drug Action 370
18.3 Pharmacodynamic Pharmacogenetics 373
  18.3.1 Pharmacodynamics and Targets for Drug Action 373
  18.3.2 Genetic Variability that Indirectly Alters Drug Response 376
  18.3.3 Adverse Drug Reactions 378
18.4 Conclusion: Pharmacodynamic Pharmacogenomics into Clinical Practice 379
Glossary 380
Acronyms and Abbreviations 381
References 381

18.1 OVERVIEW

Drug response or adverse effect is the net effect of multiple factors: age, organ function, concomitant therapy, drug interactions, and disease. In addition to these, there are now numerous examples of cases where interindividual differences in drug response are due to sequence variants in genes encoding drug-metabolizing enzymes, drug transporters, or drug targets. The study of the biochemical and physiological interactions between drugs and their targets and the relationship between plasma drug concentration and drug effect is known as pharmacodynamics. The genetic determinants of drug response are potentially of great clinical value as, unlike other factors influencing drug response, they generally remain stable throughout a person's lifetime. This chapter focuses on the principles of pharmacodynamics and how genetic variation of drug targets can have an effect on drug response.

18.2 BASIC PHARMACODYNAMICS

Pharmacodynamics describes the relationship between the drug concentration at the receptor and the physiological and biochemical effect produced. Pharmacodynamics is often described as "what the drug does to the body."

18.2.1 Historical Aspects

> *If you want to explain any poison properly, what then isn't a poison? All things are poison, nothing is without poison; the dose alone causes a thing not to be a poison.*
>
> Paracelsus 1493–1541 A.D.

Medicines have been used for thousands of years, initially in the form of minerals and plants observed to have therapeutic effects without any understanding of the mechanism behind them. Paracelsus (Theophrastus von Hohenheim, 1493–1541) was a Swiss physician, botanist, alchemist, and astrologer. He was the first to question the effects of prescribed medicines and sought knowledge of the active ingredients and the theory behind their mechanisms of action while rejecting irrational compounds. Paracelsus went on to explain the initial effects of dose and adverse effects, and this was the beginning of what has grown to become the modern pharmacodynamic theories of dose-concentration-response relationships and the concept of the therapeutic index.

Handbook of Pharmacogenomics and Stratified Medicine. http://dx.doi.org/10.1016/B978-0-12-386882-4.00018-9

Johann Jakob Wepfer (1620–1695), a Swiss pharmacologist and pathologist, was the first to use animal experimentation to verify theories about pharmacological actions, studying the effects of water hemlock, hellebore, and monkshood. His studies paved the way for the current practice of preclinical studies to test new drugs in humans.

Human studies were carried out in 1805 by Friedrich Sertuner, a German pharmacist who isolated the first alkaloid from opium and administered a large dose to himself and three acquaintances, all of whom suffered symptoms of severe opioid toxicity.

Oswald Schmeideberg (1838–1921), a Russian pharmacologist, helped to establish pharmacology as an independent science discipline. His thesis concerned the measurement of chloroform in blood, and he earned a medical doctorate at the University of Dorpat. Together with his working group, he discovered and described fundamental concepts in clinical pharmacology and pharmacodynamics, including structure–activity relationships (T. Frazer 1841–1921), drug–receptor relationships (J. Langley 1852–1925), and the emerging field of toxicology (P. Ehrlich 1854–1915). Alexander J Clark, an English pharmacologist, formalized receptor theory when the law of mass action was applied to drug–receptor theory in the 1920s.

The organ bath is currently used as standard for *in vitro* pharmacodynamic dose–response experiments involving the suspension of an isolated section of organ/tissue in a controlled solution with sensors to measure the contraction or relaxation of the tissue when drugs are added. The organ bath experiment was used by Henrick Magnus (1802–1870), who applied the method to a strip of small intestine. He was followed by Jean Francois Heymans, who in 1904 worked with the mammalian heart.

The first chair in pharmacology was established in 1890 in the United States at the University of Michigan under John Jacob Abel, who was an American pharmacologist trained by Oswald Schmiedeberg. Since the 1960s, departments of pharmacology and clinical pharmacology have been established in many universities.

As knowledge of clinical chemistry and pharmacology grew, the principles of these disciplines were applied to the pharmaceutical industry and particularly in drug development. Drugs are now designed to interact with known targets to produce therapeutic effects. Squibb developed captopril, whose structure was designed to fit the active site of the angiotensin-converting enzyme. This lead to the further development of the current ACE inhibitor class of drugs.

Pharmacology and the study of pharmacodynamics principles have been prominent throughout history, and the evolution of pharmacogenomics provides a new and exciting field.

18.2.2 Basic Principles

The functional macromolecular component of an organism that is presumed to interact with the drug is termed a receptor. However, even if a drug interacts with a specific molecular receptor and stable drug and metabolite concentrations are maintained, it does not imply that the drug effect will be constant over time. This is because the drug–receptor interaction is influenced by multiple factors, including physiologic milieu, concomitant disease, and drug effect. For example, receptors may be up- or downregulated by either the disease or the drug itself affecting drug efficacy and toxicity.

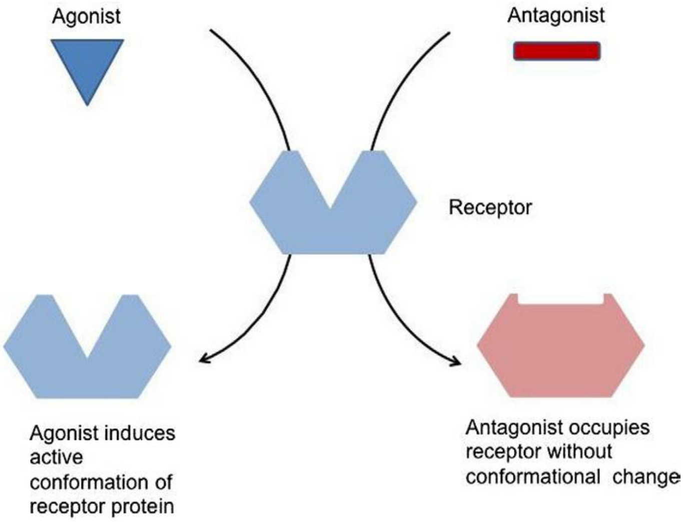
18.2.3 Receptors

Receptors are the key part of the signaling system that enable coordination of the activities of cells and organs. A receptor is a macromolecule, or an assembly of macromolecules, located in the cell membrane or within the cell that binds ligands (endogenous molecules or exogenous drugs) resulting in chemical signaling between and within cells with consequent pharmacological effects [1]. There are 646 genes, to date, that are known to encode for receptors [2]. The International Union of Basic and Clinical Pharmacology (IUPHAR) database contains pharmacological, physiological, and genetic information on human and rodent receptors, other drug targets, and the substances that act on them [2]. It is updated regularly.

Physiological receptors are proteins that act as receptors for endogenous ligands, and they tend to be highly selective. Drugs that act on physiological receptors can mimic the response of the endogenous ligand (agonist) or bind to the receptor, causing no effect but preventing endogenous ligand binding (antagonist), or they can mimic the response of the endogenous ligand to a limited extent but also prevent any further stimulation (partial agonist) [1]. Figures 18.1 through 18.3 and Table 18.1 illustrate the effect of agonists and antagonists on receptors. The strength of the reversible interaction between the drug and the receptor (the agonist dissociation constant (K_D)) is defined as the affinity of one for another [1]. Affinity is determined by the drug's chemical structure.

18.2.3.1 Mechanisms by Which Drugs Act on Receptors

Drugs can interfere with the usual function of the receptor at a site determined by the receptor's location. The effect of the drug is partly determined by the functional capacity of the receptor [1]. Receptors can mediate functions common to many cells and consequently the effect of a drug on a receptor is widespread and may result in more frequent unwanted effects [1]. If a drug acts on a receptor that is unique to one or a few cells, the effects will be more specific; however, the physiological consequences may still be widespread [1]. The ideal drug acts only in the receptor of interest at all concentrations and does not have any interaction with other receptors or biological systems at any concentration. However, there are no drugs with this ideal property.



Agonist
Antagonist
Receptor
Agonist induces active conformation of receptor protein
Antagonist occupies receptor without conformational change

FIGURE 18.1 Action of agonist and antagonist on receptor.

FIGURE 18.2 Conformation of receptor following agonist and antagonist binding.

Receptors have two functions with specific domains: ligand binding (ligand-binding domain) and cell signaling (effector domain) [1]. The actions of a receptor may be directly on cellular targets, effector proteins, or intermediary cellular signal molecules (transducers) [1]. The receptor, target, and intermediary signaling molecule together are referred to as the signal transduction pathway. Often, the effector protein acts as an enzyme or transport protein that creates, moves, or breaks down a metabolite or ion. In this case, it is known as a second messenger. A second messenger is a molecule that relays signals from receptors to target molecules within the cell.

Second Messengers

An agonist binding to a receptor, considered the first messenger in receptor signal transduction, promotes mobilization of a second messenger [1]. Second messengers are molecules that relay signals from receptors on the cell surface to target molecules in the cytoplasm or nucleus [1]. They amplify the strength of the signal and can influence each other's metabolism [1]. Second messengers' essential properties are summarized as follows:

- The increase in second messenger levels is produced by the appropriate agonists and blocked by specific antagonists.
- The increase in second messenger levels precedes the increase in response.
- The response to an agonist can be mimicked by an exogenously applied second messenger.
- Substances that block the breakdown of the second messenger potentiate the response.

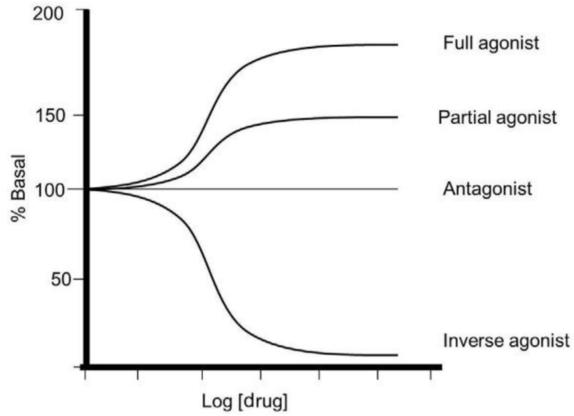

FIGURE 18.3 Action of full agonist, partial agonist, antagonist, and reverse agonist.

18.2.3.2 Types of Receptors

Receptors are classified into four types that exhibit characteristic properties. These are described in the following subsections.

Receptor Protein Kinases and Guanylyl Cyclases

Cell surface protein kinases are a group of receptors with intrinsic enzymatic activity. They exert their effect by phosphorylating diverse effector proteins on the inner side of the plasma membrane [1]. Phosphorylation is a common mechanism for facilitating the biochemical activities of an effector or its interaction with other proteins [1]. The majority of receptor protein kinases are composed of an agonist binding site on the extracellular surface of the plasma membrane, a solitary membrane-spanning element, and a protein kinase domain on the inner surface of the membrane. Other variations include the assembly of multiple subunits or multiple binding domains. Figure 18.4 illustrates the different receptor types and structures.

TABLE 18.1 Agonist and Antagonist Effects

Action	Effect
Agonist	Stimulates or activates the receptor to produce an effect
Antagonist	Prevents the action of an agonist but does not have any effect itself
Partial agonist	Stimulates the receptor to a limited extent but also prevents any further stimulation by naturally occurring agonists
Inverse agonist	Produces an effect opposite to that of the agonist

Receptors that bind guanylin and uroguanylin have a guanylyl cyclase intracellular domain, rather than a protein kinase domain, that synthesizes the second messenger molecule cyclic guanosine monophosphate (cGMP). This activates a cGMP-dependent protein kinase and can modulate the effects of effectors.

G protein Coupled Receptors

G protein–coupled receptors (GPCRs) are the largest family of receptors. They have distinct GTP-binding regulatory proteins known as G proteins. These act as cell-signaling molecules conveying information from the GPCR to a single or multiple effector proteins [1]. GPCRs are the target for many drugs and span the plasma membrane with seven transmembrane domains, an extracellular N-terminal domain, and an intracellular C-terminal domain [1]. The structure and function of GPCRs are shown in Figure 18.4. The G protein families and their effects are listed in Table 18.3; the three GPCR families are summarized in Table 18.4. The targets of GPCRs are summarized in Table 18.5.

For example, catecholamines (first messengers) activate β adrenoceptors to increase, through a G-protein coupled system, the activity of intracellular adenylate cyclase, which increases the rate of formation of cAMP (second messenger), which is a modulator of the activity of several enzyme systems that cause the cell to act.

Ion Channels

Ion channels allow the selective passage of selected ions through the cell membrane and can be opened or closed through a number of different mechanisms [1]. The receptor can exist in an open or closed state. Drugs may open or close the ion channel by binding to the channel protein, or they may affect the function indirectly by involving a G protein or another intermediary [1]. There are two main types of ion channel: ligand-gated ion channels, which open when an agonist is bound and can be considered a receptor; and voltage-gated ion channels, which open in response to alterations in transmembrane potential [1]. Voltage-gated ion channels are not strictly receptors as they do not require agonist binding to open and can be considered drug targets [1].

Ion channels are large structures with several similar or identical domains organized in an array of subunits or as a single large protein. Each subunit contains 2–6 transmembrane domains. Ion channels are selective to particular ion species, generally cations (Na^+, Ca^{2+}, K^+) or anions (Cl^-). They are the only way by which ions can cross the cell membrane, as they are unable to penetrate the lipid bilayer [1]. Ion channels are made up of protein molecules that form water-filled pores that span the cell membrane and can be opened or closed [1]. Different ions pass through different ion channels at different speeds depending on the electrochemical gradient. The gating and permeation of the ion channels is modulated by ligands binding to various sites

on the channel protein, mediators, and drugs acting in an indirect way, often through GPCR and second messengers in intracellular signaling pathways [1]. The structure and effects of a ligand-gated ion channel is shown in Figure 18.4.

Nuclear Receptors

Nuclear receptors are monomeric proteins with a core domain, N-terminal domain, C-terminal domain, and activation function site [1]. There are two classes of nuclear receptor (see Table 18.2). Steroid (estrogen, glucocorticoids) receptors located in the cell cytoplasm are translocated into the nucleus following binding with their steroid partner or located within the nucleus [1].

TABLE 18.2 Classes of Nuclear Receptor

Class I	Class II
Present in cytoplasm	Present in nucleus
Operate as homodynes	Operate as heterodimers
Endocrine ligands	Lipid ligands
High affinity	Low affinity
Glucocorticoid receptor, estrogen receptor	PPAR, RXR

TABLE 18.3 G Protein Families and their Effects

G protein	Effect
Gs	Activates adenylate cyclase
Gi/Go	Inhibits adenylate cyclase
Gq	Activates phospholipase C

Hormone response elements are short sequences of DNA to which nuclear receptors bind to modify gene transcription. Once inside the nucleus, the ligand-bound receptor modifies gene expression through its AF domains by recruiting co-activators. This is illustrated in Figure 18.4.

Enzymes

Interaction between a drug and an enzyme can be considered similar to that between a drug and a receptor. Drugs can alter enzyme activity because they are manufactured to resemble a natural substrate and therefore compete with the natural substrate for the enzyme-binding site. The action can be competitive and reversible in the case of enalapril. Enalapril is structurally similar to angiotensin I and occupies the site of angiotensin I on the angiotensin-converting enzyme (ACE), it thus inhibits ACE. Alternatively, the action can be irreversible in the case of aspirin, which combines covalently to cyclooxygenase (COX) and inhibits the enzyme in platelets for the duration of their lifespan [1].

Transport Receptors

Transport receptors are a specialized class of receptors transmitting molecular material rather than information. Transport of ions and small molecules across the cell membrane requires a carrier protein, as these molecules have insufficient lipid permeability or too high a polarity to cross the membrane by themselves [1]. The transport receptors have a specific recognition site that allows only a specific molecule or family of molecules to be transported. An example of a transport receptor is LDL.

18.2.3.3 Receptor Binding, Dose-Response, and Regulation

Receptor binding can be weak and rapidly reversible (e.g., hydrogen bonds) or strong and effectively irreversible (e.g., covalent bonds). Receptor numbers do not remain constant

TABLE 18.4 G Protein Coupled Receptor Families

but differ according to circumstances. When tissues are continuously or repeatedly exposed to an agonist, the number of receptors decreases (downregulation), which may be a cause of tachyphylaxis (the loss of efficacy with frequently repeated doses) [1]. The continuous or prolonged exposure to an antagonist leads to an increase in receptor numbers (upregulation), which is the reason for side effects associated with abrupt withdrawal of some drugs (e.g., β adrenoceptor blockers) [1].

The binding of drugs to receptors can often be measured directly by incubating samples of tissue with various concentrations of drugs, which are radioactively labeled (3H, 14C, 125I), and then waiting until equilibrium is reached. The amount of radioactivity is measured following the removal of the supernatant. There is usually some nonspecific binding where the radiolabeled drugs are taken up by structures other than the receptor of interest. The amount of nonspecific binding is estimated by a further experiment in which the radiolabeled drug is taken up in the presence of a saturating concentration of a nonradiolabeled receptor antagonist; the nonspecific binging proportion is measured. The specific binding is the total binding minus the nonspecific component. A binding curve is drawn to enable the affinity of the drug for the specified receptor and the binding capacity (B_{max}) to be estimated. This is illustrated in Figure 18.5 [1]. Binding curves for agonists often show drugs binding to two or more receptors with different affinities. Binding capacity is the density of receptors within the tissue. Positron emission tomography (PET) can be used to investigate the distribution of receptors within organs.

18.2.4 Measurement of Drug Action

The effect of a drug can be measured either by laboratory measurements or clinical outcomes. This section describes the relationship between drug dose and pharmacological response and mechanisms of drug response.

18.2.4.1 Dose–Response Relationship

The effect of a drug (e.g., drop in blood pressure or contraction of smooth muscle) can be determined using clinical or laboratory measurements. The results are then plotted against the dose or concentration that the recipient or section of tissue is exposed to. This is known as the dose–response curve *in vivo* and the concentration-effect curve *in vitro* [1]. A steep curve suggests that a

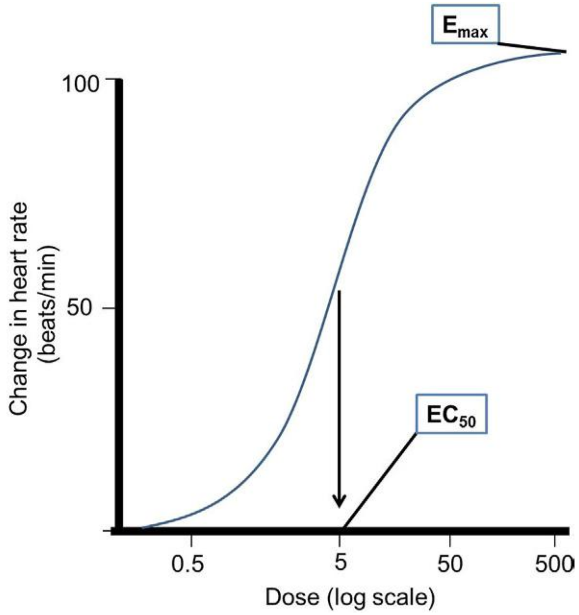

FIGURE 18.6 Dose–response curve showing ED_{50}.

small change in dose will produce large effects in clinical response or adverse effects; a flat relationship suggests that increasing the dose will provide little clinical advantage (see Figure 18.6). The dose-response curve and the concentration-effect curve allow estimation of the maximum response that the drug can produce (i.e., no further clinical effect will be gained by further increasing the dose) and the dose or concentration required to produce 50% of the maximum effect (ED_{50} or EC_{50}) [1]. Dose-response and concentration-effect curves cannot be used to estimate binding or affinity.

Although the concentration-effect curve is useful, it must be recognized that the concentration of the drug in solution may differ from its concentration at the receptors, as it will be subject to degradation, transport, and metabolism and may have already reached steady state.

18.2.4.2 Therapeutic Index

The therapeutic index is the relationship between the therapeutic and toxic dose of a given drug and is calculated using the ED_{50} and TD_{50}:

$$\text{Therapeutic Index} = TD_{50} / ED_{50}$$

ED_{50} is the dose required to produce a therapeutic effect in 50% of the population; TD_{50} is the dose required to produce a toxic effect in 50% of the population; both are calculated from dose–response curves. The therapeutic index is shown in Figure 18.7.

The dose of a drug can be increased progressively until a desired response is achieved; however if it is further increased, no additional desired effects are achieved and unwanted effects can be seen. Drugs with a narrow therapeutic index can be difficult to use in clinical practice and often require monitoring of plasma concentration in order to prevent toxicity [1]. Some examples of drugs with a narrow therapeutic index are as follows:

- Warfarin
- Lithium
- Digoxin
- Phenytoin
- Gentamicin
- Amphoteracin B
- 5-fluouracil
- Zidovudine

18.2.4.3 Competitive Antagonism

Unlike in clinical trials, the reality of modern medicine is that a drug's effect cannot be considered in isolation, as a large number of patients will be exposed to multiple drugs that can influence each other's effect in multiple ways. One common mode of drug interaction is competition for binding at the receptor site. When a competitive antagonist is

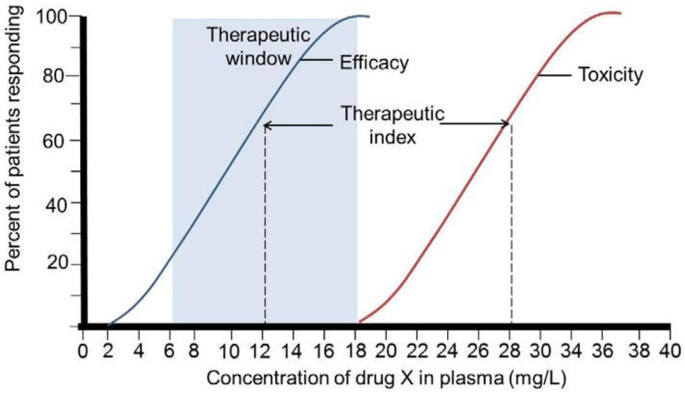

FIGURE 18.7 Therapeutic index.

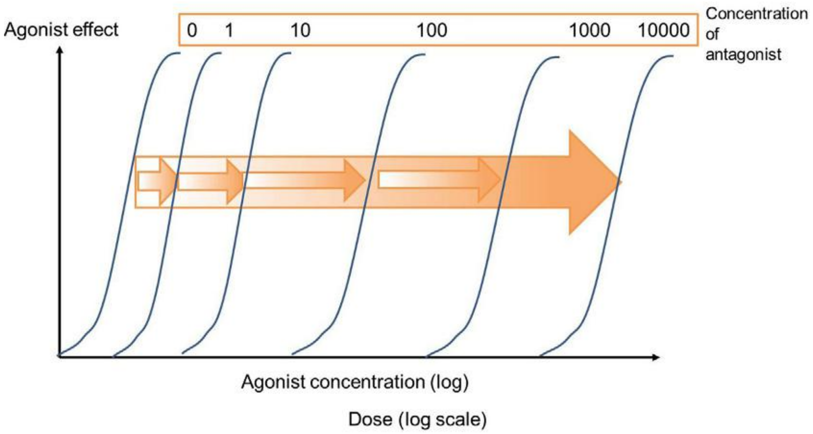

FIGURE 18.8 Agonist levels versus agonist effects in the presence of increasing antagonist levels.

present, the concentration-effect curve is shifted to the right with no change in slope or maximum concentration; this principle is illustrated in Figure 18.8 [1].

The agonist occupancy rate at a given agonist concentration, in the presence of a competitive antagonist, will be reduced because the receptor can bind only one molecule at a time. Given the nature of competition, increasing the antagonist concentration can restore agonist occupancy, making the competitive antagonism surmountable. In noncompetitive antagonism, increasing the agonist concentration does not restore agonist occupancy, making the antagonist effect insurmountable. Displacement of the competitive antagonist occurs because the agonist, by occupying the vacant receptors, reduces the rate of antagonist binding. Irreversible antagonism does occur (e.g., aspirin and monoamine oxidase inhibitors), and these drugs bond covalently to the receptor. The characteristics of competitive antagonism are as follows:

- Evidence of competition displayed during binding studies
- Shift of the concentration-effect curve to the right, without change in slope or maximum effect
- Linear relationship between agonist dose ratio and antagonist concentration

18.2.4.4 *Allosteric Modulation*

In addition to the specified agonist binding site, receptors can also have many other binding sites through which drugs can alter receptor function by increasing or decreasing receptor affinity for agonist binding or by altering efficacy [2]. These binding sites are referred to as allosteric, and ligands may be allosteric facilitators of the agonist effect or allosteric antagonists [2].

18.2.4.5 *Efficacy and Potency*

Efficacy is related to the ability of the agonist to activate the receptor. Full agonists have a high efficacy while antagonists have a low efficacy. Efficacy is related to receptor occupancy: compounds with low efficacy are required to occupy more receptors to produce the same response compared to those with higher efficacy. Full agonist efficacy is variable, as different agonists may require occupation of a different number of receptors to produce a maximum response. Intrinsic activity refers to the relative ability of a drug receptor complex to produce a maximum response effect. The intrinsic activity of a full agonist is always 1 while the intrinsic activity of an antagonist is always 0 because they bind to receptors but do not produce any effect. Partial agonists have an intrinsic activity between 0 and 1.

Potency is a measure of drug activity expressed in terms of the quantity required to produce a given effect—that is, the amount (weight) of a drug in relation to its effect. For example, if the weight for drug X has a greater effect than the weight of drug Y, even if the maximum therapeutic effect is similar with both drugs, drug X is said to be more potent [1].

18.2.4.6 *Desensitization and Tachyphylaxis*

Repeated exposure to a drug may result in a reduction of effect. Receptor numbers do not remain constant but differ according to circumstances. This can be due to receptor up-or downregulation. Desensitization and tachyphylaxis can occur very quickly; however, tolerance describes a reduced effect over a longer period of time [1]. The mechanisms by which desensitization, tachyphylaxis, and tolerance occur are described in the following sections.

Change in Receptors

Desensitization occurs rapidly in receptors coupled to ion channels and is caused by a conformational change in the receptor that results in tight binding of the agonist without opening of the channel [1]. A second mechanism is the phosphorylation of intracellular regions of the receptor protein, which is a slower mechanism. GPCRs also show desensitization. Second messenger cascades are not activated, although the agonist is bound, because receptor phosphorylation occurs [1]. This uncoupling mechanism happens over a few minutes.

Translocation of Receptors

Repeated or prolonged exposure to a drug results in a gradual decrease in receptor numbers expressed on the cell surface. This is a result of internalization of the receptors and occurs within hours. The internalized receptors are moved into the cell by endocytosis of sections of the cell membrane. Internalization is phosphorylation dependent [1].

Alterations in Drug Metabolism

Tolerance to some drugs occurs because repeated exposure to the same dose causes a lowering of plasma concentrations as a result of metabolic degradation [1].

Exhaustion of Mediators and Physiological Adaptation

If essential intermediate substances are depleted, desensitization can occur. For example, a drug's effect on the body may be nullified by homeostatic responses, causing desensitization [1].

18.2.4.7 Non-Receptor-Mediated Drug Response

Although the majority of drugs act through receptors, some exert their effects through other pathways or simply by being in an appropriate area of the body. Osmotic laxatives draw fluid from the bowel without binding. Chelating agents bind directly with heavy metals. Osmotic diuretics (mannitol) inhibit reabsorption of Na^{2+} and water in the renal proximal tubule by increasing osmolality of the tubule fluid, resulting in volume expansion.

18.3 PHARMACODYNAMIC PHARMACOGENETICS

Pharmacodynamic pharmacogenomics is the study of variations in genes encoding drug targets that can affect target protein function, a drug-target interaction that produces profound effects on drug response. As noted by Sir William Osler (1849–1919):

> *Variability is the law of life, and as no two faces are the same, so no two bodies are alike, and no two individuals react alike, and behave alike under the abnormal conditions which we know as disease.*

The following sections describe some examples of the importance of pharmacodynamics in the genetic determination of drug response and toxicity.

18.3.1 Pharmacodynamics and Targets for Drug Action

The effect of a drug is a result of their interaction with the receptor, which alters its function and initiates a cascade of physiological and biochemical changes. Here we look at some examples of genetic variations in drug targets that affect their pharmacodynamics.

18.3.1.1 Statins

Statins are competitive inhibitors of hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase, which is the enzyme that controls the rate-limiting step of cholesterol synthesis. While the majority of patients on statins respond with a 30–50% LDL cholesterol reduction, there is wide (10–70%) variability in response. Genetic variation can result in alternative splicing of *HMGCR*, resulting in reduced LDL lowering, as the variant *HMGCR* is less sensitive to statins [3–5]. (See Chapter 31).

18.3.1.2 Antiplatelet Drugs

Aspirin

Aspirin is well established for primary and secondary prevention of cardiovascular diseases. It causes irreversible acetylation of serine at position 530 of platelet cyclooxygenase-1 (COX-1), the enzyme that catalyzes the conversion of arachidonic acid to prostaglandin G2 (PGG2). This procss is followed by conversion to thromboxane A2 (TXA2), which functions as a potent vasoconstrictor and platelet activator through binding to the TXA2-specific platelet receptor. With adequate dosing and compliance, aspirin is capable of completely inhibiting COX-1 in >99% of patients, and platelets exposed to aspirin are essentially permanently disabled from generating TXA2 and are inhibited throughout their lifespan (approximately 7–10 days) [6]. Even though aspirin disables COX-1-dependent activation, platelet activation can proceed along pathways that are COX-1 independent or only partly dependent. Alternate agonists such as adenosine diphosphate and collagen can produce robust aggregation in the face of complete COX-1 inhibition [7]. This phenotype demonstrates characteristics that make it attractive for pharmacogenetic studies—wide interindividual variability [8], heritability ($h^2 = 0.27 - 0.76$) [9], and association with future cardiovascular events at high levels [10].

The term "aspirin resistance" has been used to describe the lack of pharmacologic drug effects measured by various platelet function tests (e.g., bleeding time, measurement of thromboxane levels and aspirin- or collagen-induced platelet aggregation) or the occurrence of recurrent atherothrombotic events despite drug treatment. Because aspirin uniformly inhibits its target, COX-1, there are probably no pharmacogenetic effects on PK/PD. Studies of genetic variants in the COX-1 gene and indirect COX-1 pathways (*PEAR1*, integrin β3, *GPVI*, *F2R*, and *GP1BA*) have not been validated, and the results are inconclusive [6]. In summary, there is currently no role for genetic testing for aspirin.

Clopidogrel

Thienopyridines are effective antiplatelet agents in patients with acute coronary syndrome (ACS) and percutaneous coronary intervention (PCI). Platelet function in response to clopidogrel is variable [11] and heritable ($h^2 = 0.73$) [12], indicating a genetic basis. Clopidogrel pharmacogenetics has identified drug response variants in genes affecting both its pharmacokinetics (*CYP2C19*, *CYP2C9*, *ABCB1*, *PON1*) and pharmacodynamics (*P2RY12*). A clear relationship has been established between variants in *CYP2C19* and clopidogrel efficacy in terms of platelet inhibition and serious adverse cardiovascular (CV) events [13]. However, one candidate gene study reported that carriers of a common *P2YR12* haplotype (rs6798347, rs6787801, rs9859552, rs6801273, rs9848789, and rs2046934) experienced improved platelet inhibition, although this has not been validated [14]. Unlike the variants in *CYP2C19*, those in *P2RY12* have not been consistently linked to clinical outcomes [15–17]. (See Chapter 25.)

Beta-Blockers

The pharmacological effects of beta-blockers derive from their ability to antagonize beta adrenergic receptors (β-ARs). Thus, the genes for these receptors have been a primary focus in β-blocker pharmacogenetic studies. In the cardiovascular system, there are two β-ARs that beta-blockers can antagonize: β1-AR and β2-AR, both of which are members of the G-protein–coupled receptors superfamily. The β1-AR gene (*ADRB1*) is located on chromosome 10q24–26. It encodes a 51.3 kDa protein, with 477 amino acid residues. β1-ARs are primarily found in the heart, controlling contractility and heart rate, but they are also expressed in kidney, vasculature, and adipose tissues. β2-ARs (*ADRB2*) are more widely distributed, including heart, vasculature, respiratory smooth muscle, kidney, adipose tissue, and brain. The gene consists of one exon located on chromosome 5q31–q32.

Beta-blockers are primarily used in the management of hypertension, heart failure, and coronary artery disease (see Chapter 32). Response to these drugs is highly variable with 30−60% of hypertensive patients on β-blocker monotherapy failing to achieve adequate blood pressure control [18] and approximately 25% of patients discontinuing the drug. Because of intolerance. Ethnic differences in dose response for propranolol [19] motivated pharmacodynamic genetic investigations of beta-blockers.

Variations in *CYP2D6* (pharmacokinetic) and *ADRB1*, *ADRB2*, and *GRK5* (pharmacodynamic) have received the most attention. Two variants in *ADBR1*, Ser49Gly (rs1801252) and Arg389Gly (rs1801253), lead to impaired downregulation [20] and higher signal transduction, respectively [21]. Therefore, carriers of either variant have enhanced β1-receptor activity and more beta-blocker sensitivity. Healthy volunteers and patients with hypertension who carry two Arg389 variants see a greater reduction in HR [22] or BP [23] mainly with metoprolol, although not with all beta-blockers [18] In patients with systolic heart failure treated with either metoprolol or carvedilol [24], but not bucindolol [25], carriers with two copies of the *ADBR1* Arg389 variant had significantly greater improvements in LVEF compared to the Gly389 carriers [26].

In general, carriers of the Arg389 variant have (1) enhanced HR and BP reduction. (2) larger improvements in LVEF, and (3) longer survival when treated with chronic beta-blocker therapy compared to carriers of the Gly389 variant. Although it is unlikely that beta-blocker therapy will ever be withheld for carriers of Gly389, a potential application of these findings is to consider advanced heart failure therapies (e.g., left ventricular assist devices, biventricular pacing, or transplantation) at an earlier stage in patients with the Gly389 variant [26].

Downstream of the beta-1-adrenergic receptor are G-protein–coupled receptor kinases, which are responsible for desensitization of the β1-adrenergic receptor. A Glu41Leu genetic variant in G protein–coupled receptor kinase 5 (*GRK5*), is more prevalent in African Americans. GLULeu41 resulting in more effective uncoupling of isoproterenol-stimulated responses than *GRK5*-Q41, thus producing a pharmacological-like “beta-blockade” in mice [27], albeit with no differences in atenolol-induced HR reduction in humans [28].

Because certain beta-blockers such as atenolol and carvedilol are minimally handled by CYP2D6, they may be reasonable alternates for *CYP2D6**4 carriers with metoprolol-induced bradycardia [26].

ADRB2 and Asthma

Asthma is a complex, chronic inflammatory airways disease characterized by airway hypersensitivity and airflow obstruction. However, clinical presentation can be acute and sometimes life threatening. Asthma has a known genetic link and is a widely studied disease in terms of genetics, but it has a complex etiology with interaction between genetics and environmental factors, including allergens and infections [29]. (See Chapter 25) [4].

β2 adrenoceptors are essential drug targets in asthma therapy, with inhaled long- and short-acting β2 adrenoceptor agonists being among the common prescribed therapies. The β2 adrenoceptor mediates the responsiveness of the airways, including bronchodilation, mucociliary clearance, and cholinergic neurotransmission inhibition [30]. Patients show a wide variation in response to both inhaled long-acting β2-adrenoceptor agonists (LABA) and short-acting

FIGURE 18.9 Structure of the β2 adrenoceptor.

β2 adrenoceptor agonists (SABA). Structure of the β2 adrenoceptor is shown in Figure 18.9. The *ADRB2* gene is located on the long arm of chromosome 5, a region that positively associates with asthma [31]. More than 50 genetic polymorphisms in the *ADRB2* gene have been identified that alter receptor behavior after agonist exposure, and variation may determine the extent of bronchodilator response.

A coding single-nucleotide polymorphism (SNP) in the *ADRB2* gene that results in the substitution of glycine for arginine at the 16th amino acid (Gly-16) has been associated with a more severe asthma phenotype and with variation in response to inhaled β2 adrenoceptor agonists [31,32].

In one study, children who were homozygous for Arg16 were 5.3 times more likely to show acute reversibility to SABA than those homozygous for Gly16 with heterozygous Gly16/Arg16, who show an intermediate response [33]. In another study, subjects with asthma who were homozygous for Arg16 and treated with regular SABA experienced a significant decline in morning and night time peak expiratory flow (PEF) compared with subjects who were homozygous for Gly16 [31,33,34]. There have been conflicting studies related to the Gly16 SNP and LABA use [31,35,36] (see Chapter 28).

HIV and *CCR5*

HIV infection in humans involves C-C chemokine receptor type 5 (*CCR5*, *CD195*), which is used by HIV as a coreceptor for entry into target cells, and *CCR2* (*CD192*), which is for monocyte chemoattractant protein 1. A polymorphism of *CCR2* at codon 64 (V64I) is common with an allele frequency of 10%, and 9% of Caucasians carry a 32-base pair deletion (*CCR5* Δ32) in the *CCR5* gene. The *CCR2* V64I allele has a significant impact on AIDS progression and *CCR5* Δ32 protects against HIV-1 transmission [37]. A HIV integrase inhibitor, such as maraviroc, specifically interferes with the interaction between *CCR5* and HIV. However, studies have shown no difference in virologic response to maraviroc-based antiretroviral according to *CCR5* Δ32 genotype in 982 patients genotyped in MOTIVATE (Maraviroc versus Optimized Therapy in Viremic Antiretroviral Treatment-experienced Patients) trials [38].

Cancer

Examples from cancer chemotherapy highlight the importance of pharmacodynamic genetic variation in drug response, and focused profiling is now becoming a part of routine cancer care [39] (see Chapters 20, 21, and 34). KRAS is a membrane GTPase that can activate many proteins in EGFR signaling pathways such as c-Raf and PI3K. Aberrant activation of these proteins usually causes cancer development independent of upstream EGFR signaling. Cetuximab and panitumumab are two monoclonal antibodies that were designed to inhibit the growth and survival of tumor cells with overexpressed EGFR in colon and head and neck cancers. If KRAS is actively mutated, the inactivation of EGFR by cetuximab or panitumumab will have no beneficial effect in curing KRAS-induced cancers [40]. The FDA label for these drugs recommends use only in patients with EGFR-expressing colon cancer who are KRAS-mutant negative (wild-type) [41].

Crizotinib is an *ALK* inhibitor approved to treat non-small-cell lung cancer (NSCLC). *ALK* was found to form a fusion *EML4–ALK* gene in 3–5% of NSCLC patients. This fusion gene is a constitutively activated kinase and leads to carcinogenesis. Therefore, its detection is required for the crizotinib use. In clinical treatment of NSCLC caused by *EML4–ALK*, drug resistance is linked to several tumor-specific genetic mutations in *ALK*: L1196M, C1156Y, F1174L, and G1269A [42,43]. Moreover, the FDA has recommends *ALK* positive as the indicator for prescribing crizotinib to treat patients with locally advanced or metastatic NSCLC [44]. In acute lymphoblastic leukaemia, the presence of a 9:22 translocation is an indication for imatinib. Breast cancer with amplification of HER2 shows improved response with the anti-HER2 monoclonal antibody trastuzumab or the HER2 tyrosine kinase inhibitor lapatinib. Lung cancer, melanoma, and myeloproliferative disorders tend to be sensitive to tyrosine kinase inhibitors with mutations in the respective genes *EGFR*, *BRAF*, and *JAK2* [45].

Cystic Fibrosis CFTR Mutations and Ivacaftor

Cystic fibrosis is a multisystem autosomal recessive-genetic condition affecting 1 in 2500 births in children of European decent and 1 in 32000 children of Asian decent. For people of European descent, 1 in 25 carry a cystic fibrosis mutation while 1 in 90 people of Asian descent are carriers. Cystic fibrosis results in infantile failure to thrive, accumulation of viscous mucus within the respiratory tract and recurrent infection, loss of exocrine pancreatic function, impaired intestinal absorption, infertility, and an increase in sweat chloride concentration. Treatment is supportive care, prevention and treatment of respiratory infection, management of diabetes and dietary advice, and ultimately lung and or pancreas transplant.

Cystic fibrosis is characterized by the loss of epithelial chloride transport due to mutations in the cystic fibrosis transmembrane-conductance regulator gene that encodes for the CFTR protein. The CFTR protein is a chloride channel that is usually present at the cell surface of epithelial cells [10]. The CFTR chloride channel is opened and closed by ATP binding and hydrolysis when activated by protein kinase A. CFTR normally transports chloride to regulate salt, fluid, and acid-base balance throughout the body [46]. There are more than 1900 known genetic CFTR mutations, each with varying degrees of phenotypic severity [46]. F508del is by far the most common mutation, accounting for two-thirds of cases.

CFTR is composed of two transmembrane-spanning domains that form an ion channel, two nucleotide-binding domains that form the ATP binding targets, and a regulatory domain that contains the PKA phosphorylation site [47]. CFTR structure and associated mutations are shown in Figure 18.10.

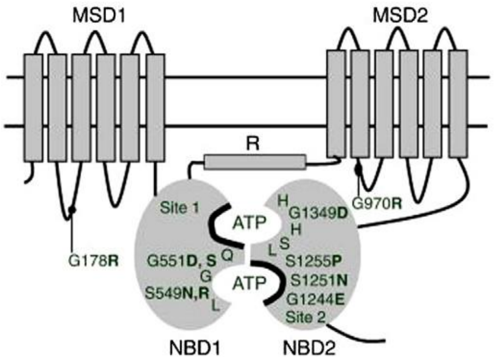

FIGURE 18.10 Structure of CFTR and associated mutations [47].

Ivacaftor is a CFTR potentiator that increases CFTR channel activity and has been shown to improve lung function in children 6 years and older with cystic fibrosis who have the G551D-CFTR gating mutation. Randomized controlled trials have shown an increase in FEV1, a decrease in pulmonary exacerbations, and a decrease in sweat chloride in patients with cystic fibrosis with at least one copy of the G551D mutation [48–50]. There was no effect seen in patients with the common F508del mutation.

Thymidylate Synthase

Thymidylate synthase (TS) is an enzyme that catalyzes the conversion of deoxy-uridylate to deoxy-thymidylate and is essential for the synthesis of DNA [51]. The human TS gene is polymorphic with either double or triple tandem repeats of the 28 base-pair sequences downstream of the cap-site in the 5′-terminal regulatory region [52]. 5-fluorouracil (5-FU) is an anti-cancer drug used in the treatment of colonic and gastric cancer that acts through its active metabolite 5-flurodeoxyuridylate, leading to the inhibition of TS. Individuals categorized as homozygous for the double repeat variant (SS) had a 50% response rate to 5-FU therapy compared to 9% in individuals characterized as homozygous for the triple repeat variant (LL) and 15% in those with the SL genotype [53]. In addition, patients with the LL genotype had less severe side effects. This indicates that genotyping patients for the TS polymorphism may lead to the ability to identify those who are more likely to benefit from 5-FU-based chemotherapy and those who are more likely to suffer from adverse drug reactions.

18.3.2 Genetic Variability that Indirectly Alters Drug Response

Changes in drug response can be a result of genetic variability, which is not directly a result of changes in drug targets or transporters and may result in altered drug efficacy or increased susceptibility to adverse drug reactions.

18.3.2.1 Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) deficiency was first described in 1956 following the development of hemolytic anemia in patients receiving primaquine therapy [54]. G6PD deficiency is the most common enzyme defect in humans, affecting approximately 400 million worldwide [55]. There are marked ethnic and geographical differences in G6PD prevalence, from <1 in 1000 in Northern Europeans to 1 in 2 Kurdish Jews. G6PD deficiency is an X-linked disorder. Although it was initially assumed to be a single-gene disorder, there are now more than 300 different known mutations. The frequency of G6PD deficiency in certain geographical areas is high because affected individuals and heterozygous female carriers have a selective survival advantage against severe malaria [55].

G6PD plays an essential role in preserving the integrity of the erythrocyte and is central in the defense against oxidative stress. The human G6PD molecule (Figure 18.11) is a dimer that provides NADPH for the antioxidant cascade in the erythrocyte [55]. The active form catalyzes the first step in the pentose phosphate pathway (PPP): the oxidation of glucose-6-phosphate to 6-phosphogluconolactone with a concomitant reduction of NAPD to NADPH [55]. NADPH is integral in protecting the erythrocyte against oxidative damage by maintaining a high level of reduced glutathione (GSH) in the cell [55]. GSH prevents oxidation of the sulfhydryl groups in hemoglobin and in the erythrocyte membrane [55]. G6PD is the only NADPH-producing enzyme that can be activated in response to oxidative stress and therefore to G6PD deficiency. NADPH concentrations are low, leading to low levels of GSH that result in oxidative damage, leading to hemolysis [55]. The pathway can be seen in Figure 18.12.

Drug-induced hemolytic anemia is a common consequence of G6PD deficiency. Many drugs have been identified as causing or potentially causing hemolysis in patients with it. Some drugs, including seven that are commonly used, are contraindicated in G6PD deficiency: dapsone, methylene blue, nitrofurantoin, primaquine, rasburicase, tolonium chloride, and phenazopyridine [56].

18.3.2.2 Factor V, Prothrombin, and the Oral Contraceptive Pill

It is well recognized that some women who take the oral contraceptive pill (OCP) are at increased risk of developing deep vein thrombosis (DVT) and pulmonary thrombosis/thromboembolism (PTE). Genetic variations associated with prothrombin and factor V have been identified and are thought to be responsible for increased risk of thrombosis in susceptible women taking OCPs [57].

Thrombin converts factor V to its active form, factor Va, which is essential for the coagulation cascade and acts as a co-factor for the conversion of prothrombin to thrombin by factor Xa. Activated protein C (APC) is a potent anticoagulant that limits coagulation by proteolytic factor Va inactivation [58]. The coagulation cascade is summarized in Chapter 23. APC resistance is associated with a seven-fold increased risk of DVT [59]. The phenotype of APC resistance is associated with the heterogenicity and homogenicity of a SNP found in exon 10 of the factor V gene (nucleotide position 1691, G to A substitution), leading to a factor V molecule (FV Leiden or FV Q506) that is not fully inactivated by APC [59].

The estrogen-containing OCP induces changes in procoagulant proteins and natural anticoagulants, leading to a state of hypercoagulability with increased fibrin production. Plasma levels of prothrombin and fibrinogen increase while factor V decreases; however, the most important effect may be acquired APC resistance [58]. These changes are evident within three months of commencing the OCP and disappear four months after withdrawal [58]. The use of the OCP by women with factor V Leiden is associated with a 17× higher risk of venous thromboembolism compared with women without factor V Leiden using no contraception [60].

A SNP in the gene encoding for prothrombin (A20210, G to A substitution) was identified as being associated with an three-fold increased risk of venous thromboembolism [61]. The risk of DVT in patients with A20210 using the OCP was increased six-fold [61].

18.3.3 Adverse Drug Reactions

An adverse drug reaction (ADR) is an unwanted or harmful reaction following administration of a medication or a combination of medications. It is suspected to be related to the drug administered. ADRs are a significant cause of morbidity and mortality worldwide [62]. They are also a significant financial burden for healthcare systems and lead to longer hospital stays [62]. Approximately 40% of patients in a community setting experience ADRs, while 6.5% of hospital admissions of adults and 2.1% of those of children are related to ADRs [62,63]. Of hospitalized patients, 6.7% suffer serious ADRs [64].

There are many examples of ADRs related to known genetic polymorphisms, and the study of these associations is often termed toxigenomics or toxigenetics. Understanding them will promote stratified medicine in the future. Generally the genes that influence drug toxicity relate to drug-metabolizing enzymes, drug transporters, and human leukocyte antigens (HLAs); see Chapters 20 and 21. Malignant hyperthermia is one example of an ADR that is related to a genetic variation of a drug target. It is discussed next.

18.3.3.1 Malignant Hyperthermia

Malignant hyperthermia is a serious and potentially fatal inherited disorder of skeletal muscle metabolism that was identified in 1985. It is triggered by commonly used volatile inhalation anesthetics and/or depolarizing muscle relaxants.

The incidence and prevalence or malignant hypertension varies greatly between epidemiological studies: from 1 in 50,000 to 1 in 100,000 anaesthetics [65]. Malignant hyperthermia is characterized by abnormalities in excitation-contraction coupling (ECC) and by the dysregulation of myoplasmic calcium levels during the activation of skeletal muscle cells. Clinical features include muscle rigidity, accelerated metabolism, lactic and respiratory acidosis, skeletal muscle breakdown leading to pyrexia, tachycardia, hyperventilation, raised PaCO$_2$, myoglobulinuria, rhabdomyolysis, hyperkalemia, and renal failure.

The ryanodine receptor gene (RYR1) encodes for the key channel that mediates calcium release in skeletal muscle during ECC [65]. Mutations in it, mapping to chromosome 19q13.2, are considered to account for susceptibility to malignant hyperthermia in more than half of cases [66,67]. To date, 80 distinct point mutations in the RYR1 gene have been found to be associated with malignant hyperthermia susceptibility [68].

RYR1 encodes for transcript is >15 kb long; however, most of the mutations linked to malignant hyperthermia are located in residues M1-R614 (MH domain 1), R2162 and R2458 (MH domain 2); a small proportion of mutations associated with MH have been linked to the COOH- terminal hydrophobic region (MH domain 3) [68]. Figure 18.13 shows the mutations identified and the associated domain. RYR1 gene mutations produce abnormalities that alter the channel kinetics, which results in channels that are hyper- and hyposensitive to activating and inactivating ligands. Most malignant hyperthermia–linked mutations cause the channels to be oversensitive [66,68].

Figure 18.14 shows how mutations linked to malignant hyperthermia affect the RYR and thus lead to alterations in calcium homeostasis. RYR1 mutations are thought to be present in 50–70% of families with a history of MH; many of the known mutations have been found only in single families, while others are more common. The G341R mutation is present in approximately 6% of Irish, English, and French families but is rare in Northern Europe, whereas the V2168M mutation is common in Swiss families but is rare elsewhere in the world [67]. RYR1 mutations resulting in increased susceptibility to MH are inherited in an autosomal dominant pattern.

Treatment of MH is with the dantrolene, a smooth muscle relaxant that acts as a ryanodine receptor antagonist. This drug has significantly reduced MH mortality from 80% in the 1970 to <5% in current clinical practice [67]. Patients who may be susceptible to malignant hyperthermia and those with a family history of it can be tested using muscle biopsy and *in vitro* contraction tests or newer tests with DNA analysis. The latter method is limited to approximately 40% of families who are eligible for DNA testing, as only certain mutations may be detected.

18.4 CONCLUSION: PHARMACODYNAMIC PHARMACOGENOMICS INTO CLINICAL PRACTICE

This chapter provides an overview of the principles of pharmacodynamics and the critical role it has in the pharmacogenetic aspects of drug efficacy and adverse reactions. This is reflected in the later chapters of this book,

where a majority of pharmacogenetic applications are based on the pharmacodynamic aspects of drugs. A good understanding of pharmacodynamic principles is essential to overcome the challenges in translating the basic science into a cost-effective, point-of-care tool for the everyday clinical setting.

Key Concepts in Pharmacodynamics Pharmacogenomics

1. Pharmacodynamics is the study of the physiological and molecular effects of drugs on their recipient and the relationship between plasma drug concentration and drug effect.
2. Large individual variability in drug efficacy and safety has been known to exist since the beginning of modern medicine; however the reasons for it have proven difficult to elucidate
3. An individual's response to a given drug depends on a complex interplay between environmental and genetic factors.
4. Pharmacodynamic pharmacogenomics is the study of altered responses to drugs that are associated with genetic polymorphisms of genes encoding for drug targets and with modifiers or key proteins.

GLOSSARY

Agonist stimulates or activates the receptor to produce an effect

Allosteric modulation indirect modulation of the effects of an agonist by binding to a separate binding site, leading to an increase or decrease in the receptor's affinity for agonist

Antagonist prevents the action of an agonist but does not have any effect itself

Desensitization repeated exposure to a drug leading to a diminishing effect

Inverse agonist produces an opposite effect to that of the agonist

Organ bath standard for *in vitro* pharmacodynamic dose-response experiments involving suspension of an isolated section of organ/tissue in a controlled solution and sensors to measure the contraction or relaxation of the tissue when drugs are added

Partial agonist stimulates the receptor to a limited extent but also prevents any further stimulation by naturally occurring agonists

Pharmacodynamics the study of the physiological and molecular effects of drugs on their recipient and the relationship between plasma drug concentration and drug effect

Polymorphism a variation in DNA sequence that is present at an allele frequency of $\geq 1\%$ of the population

Receptor a component of the organism with which a drug interacts

Second messenger a molecule that relays signals from receptors to the cell surface target

SNP single-nucleotide polymorphism—a point mutation occurring at a frequency of $\geq 1\%$

Tachyphylaxis decrease in response to a drug following repeated administration

Therapeutic index the relationship between therapeutic and toxic doses of a drug

ACRONYMS AND ABBREVIATIONS

5-FU	5-fluorouracil
ACE	angiotensin-converting enzyme
ADR	adverse drug reaction
APC	activated protein C
Bmax	maximum specific binding
cAMP	cyclic adenosine monophosphate
COX	cyclo-oxygenase
CFTR	cystic fibrosis transmembrane conductance regulator
cGMP	cyclic guanosine monophosphate
DAG	diacylglycerol
DNA	deoxyribonucleic acid
DVT	deep venous thrombosis
EC	extracellular
ECC	excitation-contraction coupling
ED$_{50}$	therapeutically effective dose in 50% of people given drug
G6PD	glucose 6 dehydrogenase deficiency
GABA	gamma-aminobutyric acid
GPCR	G-protein coupled receptor
HLA	human leukocyte antigen
IC	intracellular
IUPHAR	International Union of Basic and Clinical Pharmacology
KD$_{50}$	agonist dissociation constant
LABA	long-acting β2 adrenoceptor agonist
NADPH	nicotinamide adenine dinucleotide phosphate
OCP	oral contraceptive pill
PPAR	peroxisome proliferator-activated receptor
PET	positron emission tomography
PPP	pentose phosphate pathway
PTE	pulmonary thrombosis/thromboembolism
RYR1	ryanodine receptor gene
SABA	short-acting β2 adrenoceptor agonist
SNP	single-nucleotide polymorphism
TI	therapeutic Index
TS	thymidylate synthase
VKORC1	vitamin K epoxide reductase complex
WHO	World Health Organization

19.1 OVERVIEW

MicroRNAs (miRNAs) are short (~22-nucleotide), endogenous, noncoding RNAs that mediate gene silencing through translational repression or mRNA degradation [1]. Importantly, miRNAs are now recognized as critical regulators of gene expression. They regulate every cellular process and a large number of physiological processes [2]. Because the role of miRNAs is to fine-tune gene expression, thereby forming intricate networks, the dysregulation of miRNA function may lead to disease.

Cytochrome P450s (P450, CYP), a superfamily of hemoproteins, are the main enzymes in phase I drug metabolism. A major function of P450s is to convert nonpolar xenobiotics, including pharmaceuticals, carcinogens, and toxicants, as well as endogenous substrates such as steroids and fatty acids, into polar compounds. In addition to transcriptional regulation by transcription factors and nuclear receptors, it has been shown that P450s are directly or indirectly regulated by miRNAs. The latter mechanism impacts inter- and intraindividual variability in the metabolism of xeno/endobiotics. This chapter summarizes current knowledge of miRNA-regulating P450s and nuclear receptors, as well as the clinical significance of miRNA-related polymorphisms.

19.2 miRNA BIOGENESIS

miRNAs are first generated by RNA polymerase II as long primary transcripts called primary miRNAs (pri-miRNAs) (Figure 19.1). Each pri-miRNA forms a hairpin stem-loop structure that is cleaved by the RNase III enzyme Drosha in the nucleus, creating a precursor miRNA (pre-miRNA) that is 70–100 nucleotides in length. Then the pre-miRNA is exported into the cytoplasm by Exportin 5, processed into a miRNA duplex of ~22 nucleotides by Dicer or Argonaute 2 (Ago2), and then unwound into a single-stranded, mature miRNA. The mature miRNA, called the guide strand, is incorporated into the RNA-induced silencing complex (RISC), which is composed of Dicer, TAR RNA binding protein (TRBP) and Ago2; it then binds to its mRNA target [3]. The other strand, called miRNA* or the passenger strand, is degraded, although it is sometimes functional.

Thus, the biogenesis of miRNAs is regulated at the transcriptional and post-transcriptional levels. At the

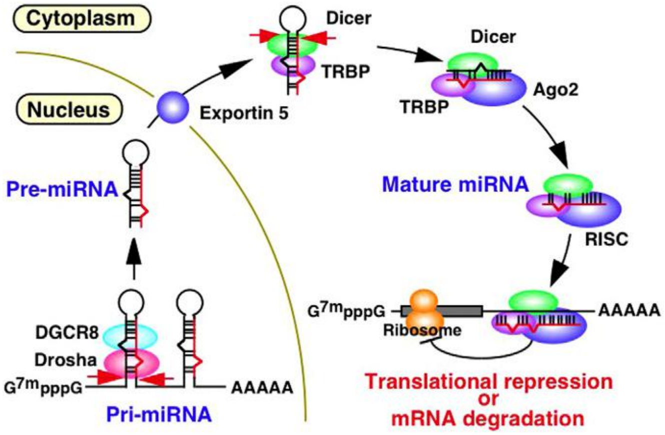

FIGURE 19.1 miRNA biogenesis and gene-silencing mechanisms. miRNA genes are transcribed by RNA polymerase II to generate pri-miRNA transcripts. The pri-miRNAs are processed by Drosha and DGCR8 in the nucleus to produce pre-miRNAs. Upon export by Exportin 5, Dicer processes the pre-miRNAs into miRNA duplexes. The duplexes are separated, and the guide strand is incorporated into miRISC, which recognizes the target mRNA and causes translational repression or mRNA degradation. *Source: Nakajima [93] with permission of the Showa University Journal of Pharmaceutical Sciences.*

transcriptional level, the production of miRNAs is controlled by mechanisms similar to those used to regulate protein-coding transcripts (e.g., transcription factors and epigenetics). At the post-transcriptional level, the biogenesis of miRNAs is regulated by miRNA processing machinery. New pathways for miRNA biogenesis have been recently reported and include the “mirtrons” pathway, in which a subset of miRNAs are derived from short hairpin introns, bypassing cleavage by Drosha, and the “simtrons” pathway, which generates splicing-independent mirtron-like miRNAs that require Drosha but not other canonical miRNA biogenesis components [4]. These recent findings suggest that regulation of miRNA expression is more complicated than expected. The control of miRNA biogenesis has been well characterized, but miRNA degradation is not fully understood. miRNAs have a long life span in general. However, the rapid turnover of miRNAs in a variety of specific cellular contexts has also been documented. Several ribonucleases that degrade miRNAs have been identified. The cellular contexts and biochemical mechanisms of miRNA decay are beginning to be uncovered [5].

To date, more than 2500 human miRNAs have been identified (miRBase, release 20, http://www.mirbase.org/). miRNAs are assigned sequential numerical identifiers [6]. Mature sequences are designated “miR,” whereas precursors are labeled “mir.” Abbreviated three- or four-letter prefixes are used to designate the species, such that identifiers take the form hsa-miR-101 (for miR-101 in *Homo sapiens*). The hsa-miR-101 in humans and the mmu-miR-101 in mice are orthologous. Paralogous miRNAs that differ at only one or two positions are given lettered suffixes (e.g., mmu-miR-10a and mmu-miR-10b). Distinct loci that give identical mature miRNAs have numbered suffixes (hsa-miR-125b-1 and hsa-miR-125b-2). The preferred method of naming guide/passenger (miRNA/miRNA*) strands designates miRNAs from 5′ or 3′ arms (e.g., miR-378-5p and miR-378-3p) [6].

19.3 miRNA FUNCTION

miRNAs function to negatively regulate gene expression via post-transcriptional mechanisms. They bind to their target mRNAs with imperfect pairing, usually in the 3′-untranslated region (UTR) or sometimes in the coding region to cause translational repression or mRNA degradation [3] (Figure 19.2). The mRNA sequence to which a miRNA binds is termed the miRNA recognition element (MRE). Gene silencing by miRNAs involves multiple mechanisms, including blocking of translation initiation, inhibition of ribosome elongation, degradation of mRNA by deadenylation or decapping, and relocalization of miRNAs associated with RISC to P-bodies, which are subcellular compartments enriched with mRNA degradation and translational repression factors [7]. miRNAs represent only 0.5–3% of the genome, but have been predicted to regulate approximately 60% of all human genes [8].

19.4 miRNA TARGET IDENTIFICATION

miRNAs bind to their targets by partial complementarity over a short sequence. During binding, nucleotides 2–8 at the 5′ end of the miRNA, called the seed sequence, (Figure 19.2), are critical [9], but perfect seed pairing alone may be insufficient. Sequences outside of the seed sequence, and even sequences outside of the MRE, can compensate or impact target regulation. Even sequences with high complementarity might not be the real targets of a miRNA. Therefore, the identification of miRNA(s) for a target gene is a challenging task. Multiple free databases (Table 19.1) are available to

predict miRNAs for target genes. These algorithms place variable weight on complementarity to the miRNA seed sequence, evolutionary conservation of the MRE in the target gene, free energy of the miRNA–mRNA duplex, and accessibility of the target site (see Table 19.2).

It is difficult to say which algorithm produces the most reliable and/or sensitive target predictions, and the use of multiple programs is recommended. In most cases, many types of miRNAs are predicted for a given mRNA, and they vary significantly depending on the program used. The false-positive rate of the predicted candidate targets of a given miRNA is thought to be 30–50% [10,11]. Therefore, experiments are necessary to confirm these predictions. The following points can be taken into consideration to select miRNAs that are to be experimentally verified: (1) the agreement of multiple algorithm results; (2) the conservation of the target site sequence among species (points 1 and 2 are neither a necessity nor a guarantee of function; (3) accessibility to the target, which seems to be a critical feature of miRNA target recognition; and (4) whether the miRNA is substantially expressed in the tissue where the target mRNA is expressed.

The overexpression or inhibition of a miRNA is an effective method for determining potential miRNA–mRNA interactions. After the transfection of a precursor miRNA or antisense oligonucleotide (AsO) into cells to overexpress or inhibit the miRNA, the protein and mRNA levels of the target are examined. Because a possible concern of the miRNA overexpression experiment is that the decrease in target expression might be artificial under nonphysiological conditions, experiments in which endogenous miRNA is inhibited with an AsO are valuable. To comprehensively determine the targets of a miRNA, it is useful to examine the changes in mRNA or protein expression by microarray or proteome analysis after miRNA overexpression or inhibition [12,13]. It should be noted that the targets identified by this analysis include secondary targets, the expression of which may change as a result of the expression changes of the primary targets. We should also note that different proteins have different turnover rates. This means that the levels of proteins with high turnover will change rapidly, whereas stable proteins will be affected at later time points. In addition, if one only examines the changes in the mRNA levels, some targets whose downregulation is caused by translational repression may be missed. Thus, changes in both mRNA and protein levels should be considered for comprehensive analysis.

To verify the interaction between a miRNA and its target mRNA, an inverse relationship between the protein (or mRNA) levels and the miRNA level is necessary—for example, in cancerous versus normal tissues or among individuals or cell lines. To examine whether the mRNA is a direct target of the miRNA, luciferase assays are useful. The reporter constructs containing the MRE of the target mRNA downstream of the reporter gene are co-transfected into cells with a precursor miRNA or AsO. Evidence of an interaction can be established when the reporter activity is significantly decreased or increased.

Different miRNAs may act together to regulate a target mRNA; this was corroborated by *in vitro* experiments. However, it is still unclear if different miRNAs act synergistically *in vivo*. In addition, the mRNA may be regulated independently by these miRNAs in different tissues or at different developmental stages, and this has been supported by *in vitro* cell-based experiments. Most studies have been performed *in vitro* using luciferase reporter systems and miRNA over- or misexpression experiments in cells. However, *in vivo* experiments to test whether individual miRNA targets are truly endogenous under endogenous conditions have been exceedingly rare.

19.5 REGULATION OF DRUG-METABOLIZING P450s

Cytochrome P450s (P450s, CYPs) are important enzymes that catalyze the detoxification of xenobiotics such as drugs, environmental chemicals, and carcinogens. The mechanisms of transcriptional regulation by nuclear receptors and the genetic polymorphism of P450s have been well studied to understand the reason for inter- and intraindividual variability in drug responses and adverse reactions, as well as xenobiotics-related toxicity. It was recently discovered that miRNAs are involved in the post-transcriptional regulation of P450s, conferring variability and modulation in drug detoxification and the metabolic activation of chemicals.

19.5.1 CYP2C8

The human CYP2C subfamily, which consists of CYP2C8, CYP2C9, CYP2C18, and CYP2C19, is responsible for the metabolism of > 20% of all clinically prescribed drugs. CYP2C protein and/or mRNA expression is at its highest levels in the human liver, but is also detected at lower levels in extrahepatic tissues such as the kidney, lung, heart, endothelium, adrenal gland, mammary gland, and brain. Numerous studies have described the transcriptional upregulation of *CYP2C* genes by xenobiotics, such as phenobarbital, rifampicin, St. John's wort, and dexamethasone. The post-transcriptional regulation of CYP2C8 by a miRNA was recently reported [14]. Potential MREs for miR-103 and miR-107 were identified in the 3′-UTR of CYP2C8 by an online search using the miRBase Targets database and TargetScan.

miR-103 and miR-107 contain the same seed sequence. When the precursor for miR-103 or miR-107 was transfected into primary human hepatocytes, the CYP2C8 protein level decreased, whereas AsO increased it. Neither the precursor nor the AsO affected the CYP2C8 mRNA level, indicating the post-transcriptional effect of these miRNAs. A putative MRE was found in the 3′-UTRs of CYP2C9 and CYP2C19, with a two- and one-nucleotide mismatch, respectively. Overexpression of miR-103 or miR-107 resulted in a decrease in the CYP2C9 and CYP2C19 protein levels in human hepatocytes, although to a lesser degree than CYP2C8 (CYP2C8 > CYP2C19 > CYP2C9).

miR-103 and miR-107, which belong to the miR-15/miR-107 group, are widely expressed in many human tissues [15]. They are transcribed from the introns of the pantothenate kinase (PANK) genes, which are involved in the regulation of acetyl-CoA levels, cell stress, insulin sensitivity, lipid metabolism, and angiogenesis. It would be of interest to examine the conditions that affect the expression of the PANK genes and the miR-103/miR-107 family and thus alter the expression of CYP2C8 and CYP2C19 in human tissues.

19.5.2 CYP2E1

Human CYP2E1 catalyzes the metabolism of low-molecular-weight xenobiotics, including drugs (e.g., acetaminophen, isoniazid, bromobenzene), organic solvents (e.g., ethanol, acetone, carbon tetrachloride, chloroform, glycerol, hexane, toluene), and procarcinogens (e.g., *N*-nitrosodimethylamine, *N*-nitrosopyrrolidine). CYP2E1 is induced by its own substrates, including isoniazid, ethanol, and acetone, through post-transcriptional or post-translational mechanisms. It is the most abundant isoform among all P450s in the human liver (56% of the total P450) at the mRNA level, followed by CYP2C9, CYP2C8, and CYP3A4 (8–11% of the total P450) [16], whereas it is the fourth most abundant isoform (approximately 7% of the total P450) at the protein level after CYP3A (30% of the total P450), CYP2C (20% of the total P450), and CYP1A2 (approximately 13% of the total P450).

It was reported that the CYP2E1 mRNA levels in 15 human liver samples were not positively correlated with chlorzoxazone 6-hydroxylase activities, which are probe activities of CYP2E1 [17]. Collectively, post-transcriptional regulation can be suggested not only for the inducible but also for the constitutive expression of CYP2E1 in the human liver.

The possibility that CYP2E1 is regulated by miRNA(s) has been studied [18]. In silico analysis identified a potential recognition element for miR-378 in the 3′-UTR of human CYP2E1 mRNA (Figure 19.3). Luciferase assays confirmed that miR-378 functionally recognizes the MRE. When the precursor miR-378 was transfected into cells expressing human CYP2E1 including its 3′-UTR, the CYP2E1 protein level and chlorzoxazone 6-hydroxylase activity were significantly decreased, but this result was not found in cells expressing CYP2E1 excluding its 3′-UTR. Interestingly, in both cell lines, the CYP2E1 mRNA levels were decreased by the overexpression of miR-378, although miR-378 did not affect the stability of the CYP2E1 mRNA. In a panel of 25 human liver tissues, no positive correlation was observed between the CYP2E1 protein level and the CYP2E1 mRNA level (Figure 19.3), supporting the

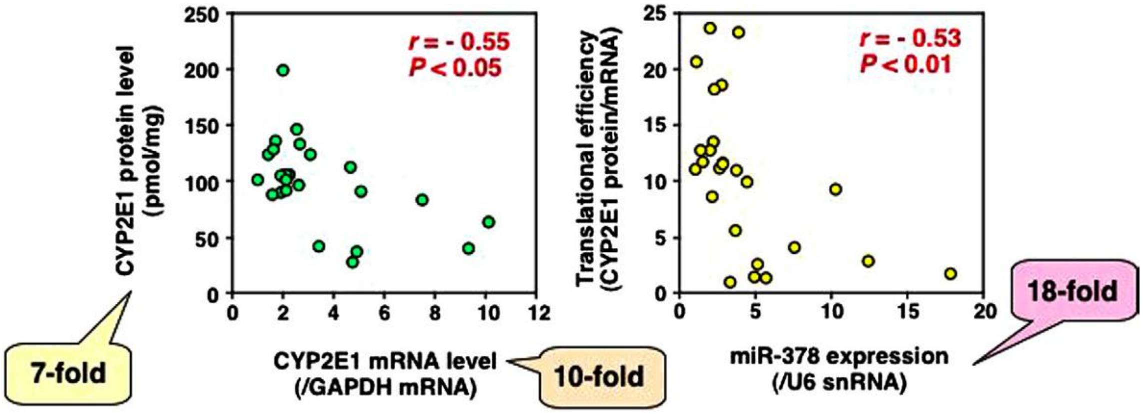

FIGURE 19.3 **Regulation of human CYP2E1 by miR-378.** miR-378 binds to the MRE in the 3′-UTR of CYP2E1 to repress its translation. In a panel of 25 human livers, no positive correlation was observed between the CYP2E1 protein level and the CYP2E1 mRNA level, whereas an inverse correlation was observed between CYP2E1 translational efficiency and the miR-378 level, indicating the impact of miR-378 on interindividual variability of human liver CYP2E1 expression. *Source: From Mohri et al.* [18] *with permission of Elsevier.*

post-transcriptional repression of CYP2E1. The miR-378 levels were inversely correlated with the CYP2E1 protein levels and the translational efficiency (protein/mRNA expression ratio) of human CYP2E1. This study provided new insight into the mechanism of the post-transcriptional regulation of CYP2E1. Because the 3′-UTR of CYP2E1 is poorly conserved among humans, rats, and mice, its regulation by miR-378 should be specific to humans.

The gene encoding miR-378 is within intron 1 of the *peroxisome proliferator-activated receptor-γ co-activator 1β* (*PGC1β*) gene on human chromosome 5q33.1 (Figure 19.4). This means that the expression of miR-378 should parallel that of *PGC1β*. *PGC1β* is a transcriptional coactivator that regulates metabolism and mitochondrial biogenesis through the stimulation of nuclear hormone receptors and other transcription factors. It has been reported that the expression of *PGC1β* is downregulated in diabetes and obesity but upregulated by insulin treatment [19,20]. In contrast, the expression of CYP2E1 is upregulated in diabetes and obesity but is downregulated by insulin treatment [21–23].

miR-378 may underlie the opposing results for *PGC1β* and CYP2E1. It was recently demonstrated that mice genetically lacking miR-378 and miR-378* are resistant to high fat diet-induced obesity, and exhibit enhanced mitochondrial fatty acid metabolism and elevated oxidative capacity in insulin target tissues [24]. Carnitine *O*-acetyltransferase (a mitochondrial enzyme involved in fatty acid metabolism) and MED13 (a component of the Mediator complex that controls nuclear hormone receptor activity), which are implicated in metabolic syndrome and obesity, were elevated in the livers of miR-378/378* knockout mice. Thus, miR-378 and miR-378* seem to be integral components of a regulatory circuit that functions under conditions of metabolic stress to control systemic energy homeostasis and the overall oxidative capacity of insulin target tissues.

19.5.3 CYP3A4

CYP3A4 is the most important P450 enzyme, as it facilitates the metabolism of a wide range of structurally different xenobiotics, including more than 50% of all clinically relevant drugs. There are large (∼50-fold) interindividual differences in the level of CYP3A4 expression in the human

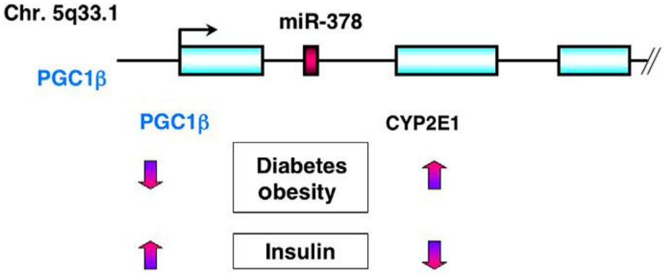

FIGURE 19.4 **Reciprocal relationship of miR-378 and CYP2E1 expression levels.** The gene encoding miR-378 is within intron 1 of the *PGC1β* gene on human chromosome 5q33.1. This means that the expression of miR-378 should parallel that of *PGC1β*, which is known as a regulator of hepatic lipid synthesis and lipoprotein production. It has been reported that the expression of *PGC1β* is downregulated in diabetes and obesity but upregulated by insulin treatment. In contrast, the expression of CYP2E1 is upregulated in diabetes and obesity but downregulated by insulin treatment. miR–378-dependent regulation may underlie the opposing changes in *PGC1β* and CYP2E1 expression.

liver and at least 6-fold interindividual variations in the activity of CYP3A4 in most populations. This variability cannot be explained solely by genetic polymorphisms [25]. CYP3A4 expression is predominantly regulated at the transcriptional level, mainly by pregnane X receptor (PXR). This idea is supported by the fact that the PXR protein level was significantly correlated with the CYP3A4 mRNA and protein levels in a panel of 25 human livers [26]. Because the CYP3A4 protein level was positively correlated with the CYP3A4 mRNA level, even if miRNA(s) are involved in the regulation of CYP3A4, their contribution may be masked by the impact of transcriptional regulation. In contrast, the PXR protein level was not correlated with the PXR mRNA level, suggesting its post-transcriptional regulation.

In this study, it was clearly demonstrated that miR-148a binds to an MRE in the 3′-UTR of human PXR mRNA to repress its translation (Figure 19.5). Because the miR-148a level in the liver panel was inversely correlated with the translational efficiency of PXR (PXR protein/PXR–mRNA ratio), miR-148a-dependent regulation can be said to be functional in the human liver, affecting the constitutive and inducible expression of CYP3A4. Interestingly, the induction of CYP2B6 (2-fold) and multidrug resistance 1 (MDR1)/P-glycoprotein (5-fold) mRNA by rifampicin, a typical ligand of human PXR, in LS180 cells was attenuated by the overexpression of miR-148a [26]. Accordingly, the miR-148a-dependent regulation of PXR appeared to affect downstream genes in common.

Furthermore, it was reported that the CYP3A4 protein level in LS180 and human pancreatic cancer-derived PANC1 cells was decreased by the overexpression of miR-27b and was accompanied by a decrease in CYP3A4 mRNA levels [27]. This finding is based only on an overexpression study. To demonstrate the importance of the miR-27b-dependent regulation of CYP3A4, an inhibition study of endogenous miR-27b, as well as a correlation analysis between the miRNA level and the target level, would be worthwhile.

19.6 REGULATION OF CANCER-RELATED P450s

Accumulating evidence shows that miRNA expression in cancer tissues is quite different from that in normal tissues. While certain miRNAs have been found to serve as oncogenes or tumor suppressor genes, these miRNAs and their contribution to the long process of cancer initiation or progression remain largely unknown. P450s catalyze the metabolic activation of a variety of procarcinogens and promutagens as well as the metabolism of endogenous compounds, including steroids, that are associated with cancer. Thus, they are associated with the initiation or progression of cancer. Some cancer-associated P450s are regulated by miRNAs, and this regulation seems to be an underlying mechanism of cancer initiation/progression.

19.6.1 CYP1A1

CYP1A1 is not constitutively expressed in liver, but it is inducible in the liver and many extrahepatic tissues, including the lung. The induction of CYP1A1 by polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls, and halogenated dioxins, which can be found in charcoal-grilled foods or the atmosphere, is dependent on the activation of the aryl hydrocarbon receptor (AhR) and

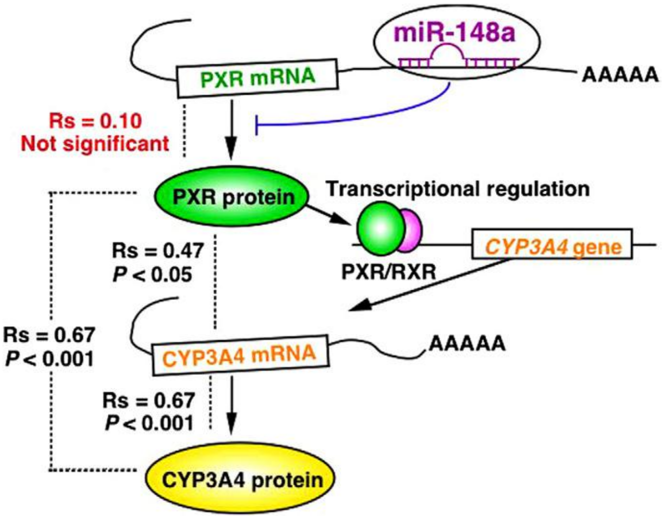

FIGURE 19.5 miR-148–dependent regulation of human PXR, affecting CYP3A4 expression in the liver. miR-148 binds to an MRE in the 3′-UTR of PXR to repress its translation. In a panel of 25 human livers, a large interindividual variability (100-fold) was found in the miR-148 expression level. An inverse correlation was observed between the translational efficiency of PXR and the expression of miR-148a. Because the PXR protein level was significantly correlated with CYP3A4 mRNA and protein levels, the miR-148a-dependent regulation of PXR is implicated as an underlying mechanism of the large interindividual variability in CYP3A4 expression.

therefore transactivation. CYP1A1 catalyzes the bioactivation of procarcinogens and proteratogens to active metabolites that bind to DNA.

It was found that miR-892a negatively regulates human CYP1A1 expression [28]. Luciferase assays revealed that an MRE in the 3′-UTR that shows a perfect match with miR-892a is functional. Overexpression or inhibition of miR-892a in MCF-7 cells resulted in a decrease or increase in CYP1A1 expression, respectively. Interestingly, benzo(*a*)pyrene, a potent inducer of CYP1A1 transcription, decreased the expression of miR-892a. The miR-892a-induced CYP1A1 repression inhibited the benzo(*a*)pyrene-mediated decrease in cell viability.

Recently, Oda et al. [29] reported that the aryl hydrocarbon receptor nuclear translocator (ARNT), a heterodimer partner of AhR, or hypoxia inducible factor 1α (HIF-1α) in the human liver, is regulated by miR-24. Overexpression of miR-24 in HuH-7 and HepG2 cells significantly decreased the ARNT protein level, but not the ARNT mRNA level, indicating its translational repression. The miR-24-dependent downregulation of ARNT decreased the expression of its downstream genes, such as carbonic anhydrase IX and CYP1A1. Taken together, CYP1A1 is directly and indirectly regulated by miRNAs.

19.6.2 CYP1B1

CYP1B1 is expressed in ovarian, uterine, and breast tissues and plays a key role in estrogen metabolism. 4-Hydroxyestradiol, a catechol-type metabolite of estradiol that is produced by CYP1B1, generates free radicals from reductive-oxidative cycling with its corresponding semiquinone and quinone forms, which causes DNA damage and contributes to estrogen-dependent cancers, such as breast and endometrial cancers. In addition, CYP1B1 catalyzes the metabolic activation of a variety of procarcinogens and promutagens, including PAHs and aryl amines. It was demonstrated that the CYP1B1 protein level is higher in various types of cancer compared with normal tissue, whereas there is no difference in the CYP1B1 mRNA levels between cancerous and normal tissues. Although there was no direct evidence to show a lack of association between the mRNA and protein levels of CYP1B1 in a panel of human tissues, these phenomena are reminiscent of post-transcriptional regulation.

Tsuchiya et al. [30] found that human CYP1B1 is post-transcriptionally regulated by miR-27b via translational repression. This was the first example of a P450 enzyme regulated by miRNA. The 3′-UTR of human CYP1B1 is uniquely long (3.1 kb), and an MRE for miR-27b was found in a highly conserved region at nucleotides 4358–4381. A luciferase assay clearly demonstrated that the MRE in the 3′-UTR, which is located in a highly conserved region between species, was functional in miR-27b binding. Interestingly, the expression level of miR-27b was lower in breast cancer tissues than in adjacent normal tissues. A significant inverse association was observed in the expression levels of miR-27b and the CYP1B1 protein between breast cancer and normal tissues. The decreased expression of miR-27b may be one of the causes of the high expression of the CYP1B1 protein in cancer tissues (Figure 19.6).

Human CYP1B1 is unique in that it has a long and complex 5′-UTR (373 nucleotides). After the study by Tsuchiya et al. [30], it was reported that the 5′-UTR of CYP1B1 interacted with the MRE in the 3′-UTR to almost completely inhibit translation [31]. It is therefore likely that the absence of the CYP1B1 protein in normal cells is due to the high degree of translational control exerted through its 5′- and 3′-UTR.

Human CYP1B1 is also regulated by estrogen receptor α (ERα) at the transcriptional level [32]. Human ERα is regulated by miR-206, and its activation results in decreased expression of miR-206, showing mutually inhibitory regulation [33]. miR-221, miR-222 [34], and miR-22 [35] were also reported to regulate human ERα expression. The effects of the miRNA-dependent regulation of ERα on CYP1B1 expression remain to be studied.

19.6.3 CYP2A

Human CYP2A13 is the major P450 enzyme in the respiratory tract. It catalyzes the α-hydroxylation of 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) and its metabolites, activating and rendering them mutagenic [36]. Therefore, CYP2A13 is critically involved in eliciting the biological effects of NNK. The orthologs of CYP2A13 in rodents are CYP2A3 in rats, and Cyp2a4 and Cyp2a5 in mice.

It was reported that the chronic administration of NNK to F344 rats for up to 20 weeks resulted in decreased expression of several miRNAs, including miR-126* and miR-34 in the lung [37]. A luciferase assay revealed that an MRE in the 3′-UTR of CYP2A3 was functionally recognized by miR-126*. In the lungs of the NNK-treated rats, the CYP2A3 mRNA and protein levels were significantly increased compared with control rats. This is a possible mechanism that may potentiate NNK genotoxicity. Because the MRE sequence for miR-126* is highly conserved among species, and because miR-126* has been suggested as a potential miRNA for human CYP2A13 by in silico programs, it is feasible that CYP2A13 is also regulated by miR-126*.

Another miRNA with clearly interesting implications is miR-34 [37], which is known to inhibit the expression of a large number of genes involved in DNA damage response, cell cycle progression, and apoptosis. The decrease in miR-34 expression after NNK exposure upregulated many genes that control important processes, such as cell proliferation and cell death, which most likely contribute to lung cancer formation [38].

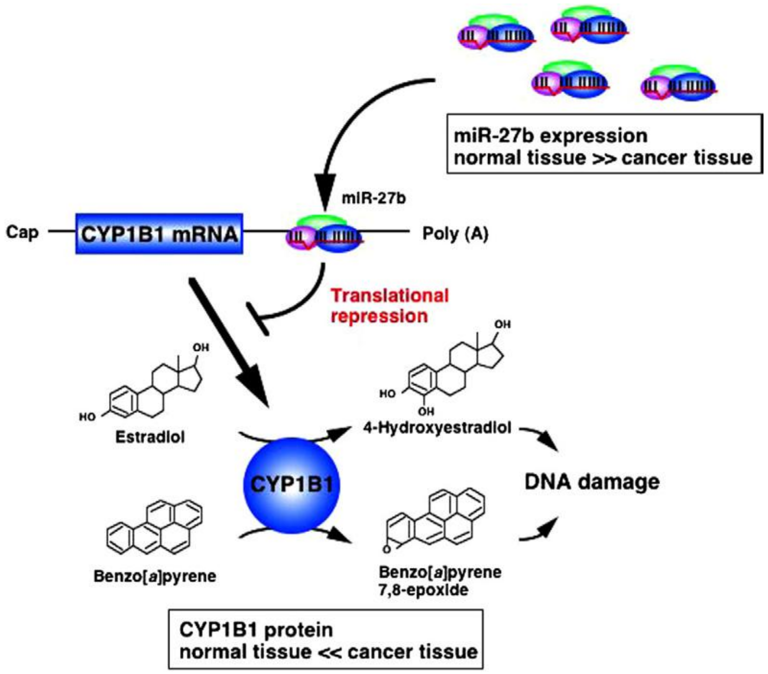

FIGURE 19.6 **Regulation of human CYP1B1 by miR-27b and dysregulation in cancer tissues.** miR-27b binds to a MRE in the 3′-UTR of CYP1B1 to repress its translation. The expression level of miR-27b in cancer tissue is lower than in normal tissue, which could be a cause of the high expression of CYP1B1 in cancer tissue.

19.6.4 CYP2J2

Human CYP2J2 is primarily expressed in the heart and vessel endothelium and is also found in a variety of tissues, including liver, lung, kidney, and gastrointestinal tissues [39]. This enzyme catalyzes the epoxidation of arachidonic acid into four regioisomers of *cis*-epoxyeicosatrienoic acid (5,6-EET, 8,9-EET, 11,12-EET, and 14,15-EET) [40]. EETs have diverse biological effects in the cardiovascular system, and they play important roles in processes related to cancer cell behavior and tumor pathogenesis. Exogenous EETs markedly accelerate the proliferation and metastasis of cancer cells *in vitro* and *in vivo*.

The association of CYP2J2 with cancer is supported by the fact that CYP2J2 is highly expressed in human tumors but not in adjacent normal tissues or nontumoral human cell lines [41]. It was demonstrated that the protein level and enzyme activity of human CYP2J2 in several cancer cell lines, including HeLa and MDA-MB-435, were significantly decreased by the overexpression of let-7b [40], a known tumor suppressor miRNA. A luciferase assay revealed that one out of seven potential MREs for let-7b in the 3′-UTR of CYP2J2 was functional for its regulation. Interestingly, an inverse correlation was demonstrated between the let-7b expression level and the CYP2J2 protein level in 18 sets of lung squamous tumor cancer and paired adjacent nontumor tissues [40]. Let-7b significantly inhibited the tumor phenotypes of tumor-xenografted mice by targeting CYP2J2. Thus, the repression of CYP2J2 was added to the list of functions for let-7b as a tumor suppressor miRNA.

19.6.5 CYP19A1

CYP19A1 (aromatase) plays a critical role in estrogen biosynthesis. To date, human CYP19A1 has been reported to be regulated by four different miRNAs: let-7f, miR-378, miR-181a, and miR-98. Xu et al. [42] demonstrated that miR-378 suppresses CYP19A1 protein expression and estradiol production in ovarian granulosa cells. A luciferase assay revealed that CYP19A1 is a direct target of miR-378. Panda et al. [43] reported that miR-98, whose aberrant expression is associated with the endometrial transition from a normal to a cancerous state, suppresses CYP19A1 mRNA and protein expression through direct interaction with its 3′-UTR in the human endometrial adenocarcinoma cell line Ishikawa. Shibahara et al. [44] reported that CYP19A1 mRNA is significantly increased in MCF-7 cells by co-culture with primary stromal cells from human breast cancer tissues, and is downregulated by subsequent treatment with letrozole, an aromatase inhibitor. In letrozole-treated MCF-7 cells, 13 miRNAs were upregulated, including let-7f, a known tumor suppressor miRNA. Multiple target-prediction algorithms suggested let-7f as a regulator of CYP19A1, and a luciferase assay revealed that an MRE in the 3′-UTR of CYP19A1 is functional, indicating that CYP19A1 is a direct target of let-7f. These results indicate that aromatase inhibitors may exert tumor-suppressing effects on breast cancer cells by suppressing CYP19A1 expression via restoration of let-7f. An inverse correlation between let-7 expression and the

CYP19A1 mRNA and protein levels in 11 breast cancer tissues supported the clinical significance of this regulatory mechanism.

19.6.6 CYP24A1

Human CYP24A1 is an essential enzyme for the inactivation of 1,25-dihydroxyvitamin D3 (calcitriol), a biologically active metabolite of vitamin D3. Calcitriol is typically considered to be a regulator of calcium homeostasis, but has received much attention for its antitumor activity. Most of the biological effects of calcitriol are elicited by its binding to the vitamin D receptor (VDR) [45]. It was demonstrated that the expression of CYP24A1 [46] and VDR [47,48] is higher in cancer tissues than in normal tissues at the protein level, but is not necessarily accompanied by an increase in the mRNA level. This suggests the involvement of post-transcriptional regulation.

Human CYP24A1 [49] and VDR [50] are both regulated by miR-125b (Figure 19.7). Because it is transcriptionally regulated by VDR, its repression by miR-125b should occur via both direct and indirect mechanisms. The miR-125b level was found to be lower in breast cancer tissues than in normal tissues, indicating a possible cause of high CYP24 expression in cancer [49]. An increase in VDR in cancer tissues would augment the antitumor effects of calcitriol, whereas an increase of CYP24A1 would attenuate them. Because the antiproliferative effects of calcitriol in MCF-7 cells were significantly abolished by the overexpression of miR-125b (Figure 19.8), it was suggested that miR-125b has a larger impact on the regulation of VDR than on the regulation of CYP24A1 in this cell system.

miR-125b is considered a tumor suppressor gene [51]. It inhibits the proliferation of human breast cancer cells [51], hepatocellular carcinoma cells [52], and thyroid carcinoma cells [53]. In contrast, its inhibition decreases the growth of human prostate cancer cells. miR-125b expression shows differential changes in human tumors—for example, it is downregulated in breast, ovarian, and bladder cancer but is upregulated in pancreatic and stomach cancer [54]. Therefore, the functional effects of miR-125b may differ between cancer types.

19.7 MODULATION OF miRNA EXPRESSION AND ITS TOXICOLOGICAL OUTCOME

Several lines of evidence indicate that miRNA expression is changed by exposure to chemicals, drugs, or hormones. It is conceivable that the up- or downregulated miRNAs may alter the expression of numerous target mRNAs, thus causing toxicological phenotype changes. It was reported that administering 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) to mice and rats caused changes in the levels of 45 and 17 miRNAs, respectively, in the liver [55]. Mouse and rat hepatoma cells in culture also exhibited changes in their miRNA levels in response to TCDD treatment [55]. Although TCDD is well known to upregulate the expression of numerous genes via AhR, it can also downregulate the expression of some genes. While researchers surmised that miRNAs might be responsible for mRNA downregulation in the TCDD/AhR pathway, it seems that mRNA downregulation is unlikely to be mediated by miRNAs and that miRNAs do not play a significant role in TCDD toxicity in the adult rodent liver.

It was demonstrated by *in vivo* and *in vitro* studies that WY-14,643, a potent peroxisome proliferator-activated receptor α (PPARα) agonist decreases the expression in mice

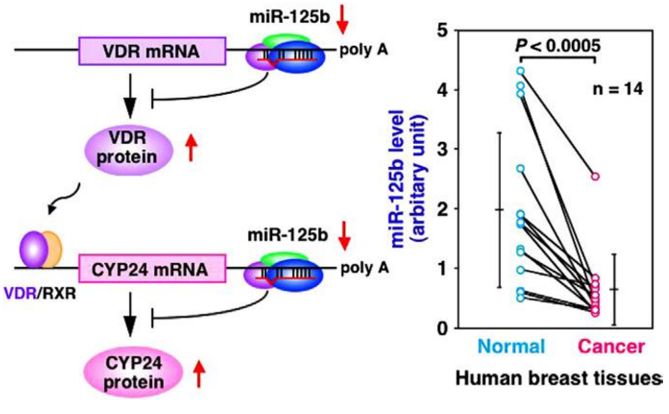

FIGURE 19.7 **Regulation of human CYP24A1 and VDR by miR-125b.** Human CYP24A1 and VDR are both regulated by miR-125b through MREs in their 3′-UTRs. Because CYP24A1 is transcriptionally regulated by VDR, its repression by miR-125b occurs via both direct and indirect mechanisms. The expression level of miR-125b in breast cancer tissue is lower than in normal tissue, which could be a cause of the high expression of CYP24A1 and VDR in cancer tissue. *Source: Nakajima* [93] *and Komagata et al.* [49] *with permission of the Showa University* Journal of Pharmaceutical Sciences *and the American Society for Pharmacology and Experimental Therapeutics, respectively.*

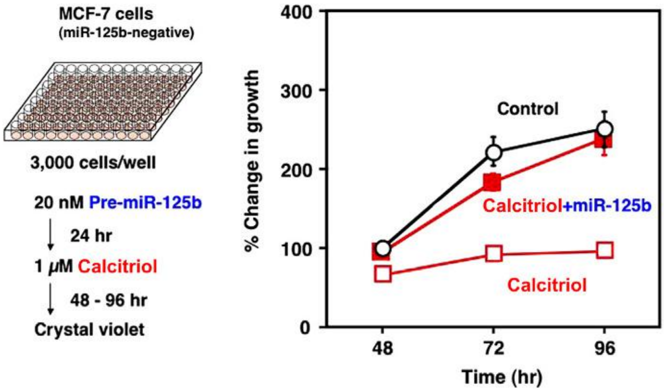

FIGURE 19.8 **Effects of miR-125b overexpression on the anti-proliferative effects of calcitriol.** The precursors for miR-125b or control were transfected into MCF-7 cells. After 24 h, the cells were treated with calcitriol for 48–96 h; crystal violet assays were then performed. The overexpression of miR-125b prominently abolished the antiproliferative effects of calcitriol. miR-125b, which regulates VDR, has a great impact on calcitriol's antiproliferative effects. In cancer cells, the downregulation of miR-125b resulted in the augmentation of calcitrol's antitumor effects.

of let-7c, which is an important miRNA in cell growth [56]. Because let-7c negatively regulates c-*myc* expression, the PPARα-mediated induction of c-*myc* via let-7c subsequently increases expression of the oncogenic miR-17-92 cluster. Thus, the let-7c signaling cascade seems to be an underlying mechanism of PPARα agonist–induced liver proliferation.

Several toxicogenomic studies have been performed to evaluate the responses or roles of miRNAs in toxicity and to establish biomarker(s) for toxicological risk assessment. Some chemicals that cause liver injury have been examined. Single administration of acetaminophen or carbon tetrachloride to rats causes changes in hepatic miRNA expression [57]. In a search for miRNAs that are decreased by two hepatotoxicants, miRNA-298 and miR-370 were identified. These are predicted to regulate thioredoxin reductase 3, an enzyme that responds to oxidative stress. Because changes in expression of these miRNAs were observed in the early phase of toxicity, they may be related to the induction of hepatotoxicity.

Chronic exposure of rats to tamoxifen, a potent hepatocarcinogen, for 24 weeks leads to substantial changes in liver miRNA expression (20 upregulated and 13 downregulated miRNAs) [58]. A significant upregulation of oncogenic miRNAs, such as the miR-17-92 cluster, miR-106a, and miR-34, was observed. In addition, the downregulation of miR-152 and miR-195, which are known to be downregulated in solid tumors [59], was found. The corresponding changes in the expression of the proteins targeted by these miRNAs, which include important cell cycle regulators, chromatin modifiers, and expression regulators implicated in carcinogenesis, were observed. These miRNA changes occur prior to tumor formation and are not merely a consequence of a transformed state.

Recently, Zhang et al. [60] demonstrated that estrogen inhibits CCl_4-induced hepatic injury through the induction of hepatic miR-29 *in vivo* in mice. Previous investigations have demonstrated that female animals are generally more resistant to CCl_4-induced fibrosis than males, owing to the protective effect of estradiol. The members of the miR-29 family, miR-29a and miR-29b, are key regulators of collagen and are implicated in tissue fibrosis [61]. Both estradiol treatment and intravenous injection of a recombinant adenovirus expressing miR-29a/b markedly attenuates the expression of fibrotic markers in mouse livers during CCl_4 treatment. This supports the protective role of estradiol-induced miR-29 in liver injury [60]. The modulation of miRNA expression by chemicals, drugs, or hormones is involved in the occurrence or mitigation of toxicological responses.

19.8 miRNA PHARMACOGENETICS ASSOCIATED WITH DISEASE OR DRUG RESPONSE

Pharmacogenetics research has matured considerably over the past few decades. Single-nucleotide polymorphisms (SNPs), the most common human genetic variants, can affect either the expression or the activity of various enzymes and may therefore be associated with differences in physiological or pharmacological outcomes. Recent genome-wide analyses of human SNPs have revealed that many of them exist in miRNA binding sites in the 3′-UTR. Approximately 400 SNPs were found at verified target sites or predicted target sites, and approximately 250 SNPs potentially create novel target sites for miRNAs in humans [62]. Such gain- or loss-of-function mutations result in changes in gene expression.

Interestingly, many examples of the association of SNPs in miRNA target sites with diseases [63] have been reported. The T>G SNP in the 3′-UTR of the *KRAS* gene, which abrogates the binding of let-7, is associated with increased risk of non-small-cell lung cancer [64]. The

G>A SNP in the 3′-UTR of the human *Slit and Trk-like 1* gene, which is implicated in Tourette's syndrome and attention deficit hyperactivity disorder, was found to strengthen the miR-189 target site, resulting in the gene's more stringent regulation [65]. A 1166A>C SNP (rs5186) in the *angiotensin receptor 1* (*AGTR1*) gene, which is implicated in hypertension and cardiovascular disease, was shown to abrogate miR-155-mediated regulation, resulting in overexpression of the AGTR1 protein [66]. The SNP in the 3′-UTR of the human *fibroblast growth factor 20* (*FGF20*) gene, which is implicated in Parkinson disease, was found to abrogate miR-433-mediated regulation, resulting in the overexpression of the FGF20 protein and its target gene α-*synuclein*, which causes Parkinson's disease [67]. The G>A SNP (rs62625044) in the 3′-UTR of the human *serotonin receptor type 3 subunit (HTR3A)* gene, which shows a strong association with female irritable bowel syndrome, was shown to abrogate miR-510-mediated regulation, resulting in the overexpression of the receptor subunit [68].

Studies of SNPs in the 3′-UTR that change the miRNA recognition of genes related to drug response are still immature. The first evidence of this phenomenon was reported for the human *dihydrofolate reductase* (*DHFR*) gene [69]. The 829C>T SNP of the *DHFR* gene (rs5030762), which is located 14 bp downstream of a miR-24 binding site in the 3′-UTR, was demonstrated to cause the overexpression of *DFHR* and methotrexate resistance [69] by evading negative regulation by miR-24. This finding suggests that sequences outside of the miRNA binding site may also be important.

However, a recent study [70] reported that the 829C>T SNP was an artifact derived from the *DHFRP1* pseudogene, which has the corresponding sequence 829T. Originally, the 829C>T SNP was genotyped by the polymerase chain reaction–restriction fragment-length polymorphism (PCR-RFLP) using cDNA samples prepared from total RNA samples that were extracted from peripheral blood mononuclear cells and a primer pair set on exons [69,71]. The *DHFRP1* gene on chromosome 18 lacks introns and has an open reading frame that is virtually identical to the coding sequence of the normal *DHFR* gene (on chromosome 5) [72]. When PCR-RFLP was performed to genotype the 829C>T SNP using genomic DNA samples with an intronic sense primer, no samples with the 829T allele were found [70]. Thus, the presence of pseudogene(s) should receive special attention with respect to genotyping and quantification at the mRNA level. The relationship between the 829C>T SNP, the DFHR mRNA level, and the involvement of miR-24 should be carefully investigated in future studies.

Another example of a SNP that affects miRNA recognition is the 973C>T SNP (rs1042157) in the *SULT1A1* gene, which encodes a sulfotransferase isoform that catalyzes the metabolism of a wide variety of endo- and xenobiotics, including dietary and environmental procarcinogens and promutagens [73]. The T allele is associated with the increased affinity of miR-631 to *SULT1A1* mRNA, leading to the gene's decreased expression.

The importance and implications of genetic polymorphisms in genes encoding drug-metabolizing enzymes are largely recognized. To date, the effects of SNPs in the coding region or 5′-flanking region on enzyme activity or expression have been eagerly investigated, but SNPs within the 3′-UTR have been largely overlooked because they are unlikely to affect enzymatic properties or expression levels. With the knowledge that miRNAs bind to sequences in the 3′-UTR, we need to reconsider the significance of SNPs in this region. Much information on human P450 variants and their outcomes has been compiled in the human cytochrome P450 (CYP) allele nomenclature database (http://www.cypalleles.ki.se/).

There are many SNPs in the 3′-UTRs of P450s. Interestingly, it has been reported that polymorphisms in the 3′-UTRs of CYP2A6 [74,75] and CYP2E1 [76] are associated with altered expression or activity. It would be of interest to investigate the possibility that regulation by miRNAs might be involved in this phenomenon. Furthermore, using in silico analysis, several research groups have reported potential miRNAs that may bind to the sequences around SNPs in the 3′-UTRs of drug-metabolizing P450s, such as CYP1A2, CYP2A6, CYP2B6, CYP2C9, CYP2E1, CYP3A4, CYP3A5, and CYP3A7, thus destroying or creating miRNA target sites [77,78]. Experimental proof is required to ascertain whether the predicted miRNAs actually regulate these P450s and so cause SNP-related interindividual variability in their expression levels.

SNPs are present not only in mRNA sequences but also in mature miRNA sequences. SNPs in mature miRNA, pri-miRNA, and pre-miRNA could modify various biological processes by influencing target selection or miRNA processing. When a SNP exists in the seed sequence of mature miRNAs, it can affect miRNA–mRNA interactions. When a SNP exists in the pri-miRNA or pre-miRNAs sequence, it may affect the expression level of the corresponding mature miRNA [79,80] and lead to modifications in target gene expression levels. Compared to the considerable level of SNPs in protein-coding mRNA, the SNPs in pri-miRNA, pre-miRNA, and mature miRNA are relatively rare. It has been reported that only ~10% of human pre-miRNAs have SNPs and that <1% of mature miRNAs have SNPs in their functional seed sequences [62].

Any given miRNA may regulate hundreds of different targets at different spatial-temporal settings. Therefore, functional mutations in miRNAs as top-level regulators are unlikely to be tolerated and are removed by purifying selection [62]. Although variations in the miRNA seed region seem to be very rare and occur with low frequency, they have the potential to influence the expression of hundreds of genes and related pathways.

In recent years, SNPs in miRNAs that alter their processing were reported to be associated with cancer risk, tumor response to anticancer agents, time to progression in cancer patients, and ulcerative colitis incidence [81]. However, in most cases, the molecular mechanism by which these polymorphisms act is not yet understood. For example, SNPs in pre-miR-196a2 (rs11614913) and pre-miR-499 (rs3746444) are significantly associated with an increased risk of breast cancer [82]. A SNP in pre-miR-27a is associated with the development of gastric mucosal atrophy in Japanese men [83]; also, a SNP in pre-miR-146a (rs2910164), which reduces premature and mature miR-146a levels, leads to a less efficient inhibition of target genes involved in the Toll-like receptor and in cytokine-signaling pathways and are associated with an increased risk of papillary thyroid carcinoma [84]. Furthermore, SNPs in pri-miR-26a (rs7372209) and pri-miR-100 (rs1834306) are significantly associated with tumor response or time to progression in 61 metastatic colorectal cancer patients treated with 5-fluorouracil and irinotecan [85]. This is the first report to reveal a relationship between the clinical outcome of drug therapy and SNPs in miRNA genes.

An important topic for future research is the effect of SNPs in miRNA sequences on drug metabolism and pharmacokinetics. A polymorphism in an mRNA target site would be target-specific, whereas a polymorphism in a miRNA may affect the expression of multiple genes and have serious consequences. The pharmacogenetics of miRNAs represents an innovative field of research for predicting drug response and toxicity. Increased knowledge of miRNA-related polymorphisms may be useful in the development of more successful individualized medicine. In this regard, the following databases are useful for investigating miRNA-related polymorphisms:

- Patrocles (http://www.patrocles.org/Patrocles.htm)
- PolymiRTS (http://compbio.uthsc.edu/miRSNP/)
- MicroSNiPer (http://cbdb.nimh.nih.gov/microsniper/)
- miRNA SNiPer (http://www.integratomics-time.com/miRNA-SNiPer/)

- miRdSNP (http://mirdsnp.ccr.buffalo.edu/)

19.9 miRNAs AS BIOMARKERS AND THERAPEUTIC TARGETS

Because of the growing evidence that a variety of diseases are associated with the dysregulation of miRNAs, miRNAs are now considered to be new tools for diagnosis and therapy [86]. Especially since the discovery of circulating and extracellular miRNAs in 2008, the study of miRNAs in body fluids, such as serum, plasma, urine, and saliva has rapidly expanded. Numerous studies have shown that circulating or extracellular miRNAs can be implicated in pathogenic conditions, such as various cancers, heart disease, diabetes, and organ damage. It is recognized that the miRNA profile of body fluids reflects the disease state as well as the presence of organ damage and injury. For this reason, circulating miRNAs are receiving much attention as a novel class of disease biomarkers.

Although the precise role of extracellular miRNAs is still largely unknown, it has also been shown that subcellular vesicles containing miRNA can be taken up by cells, causing changes in cellular gene expression in pathological conditions. These findings suggest biological functions for extracellular miRNAs that have yet to be fully investigated.

The modulation of miRNA levels is a potential therapeutic target because miRNAs are differentially expressed in diseases and play critical roles in various biological pathways. Some pioneering pharmaceutical companies have initiated the development of therapeutic candidates using miRNA mimics or inhibitors for cancer, cardiovascular diseases, neurological disorders, and viral infections. There are several ongoing clinical trials [87,88]. Because an individual miRNA could regulate several genes and pathways simultaneously, miRNA modulation could produce a powerful outcome. However, attention must be paid to the possibility that miRNA manipulation causes unanticipated effects, as the targets of each miRNA have yet to be thoroughly clarified. Although there are some hurdles to be overcome, such as stability, appropriate *in vivo* delivery systems, and selectivity, targeting miRNAs for therapy is an emerging field.

19.10 miRNAs AND DRUG RESPONSE

Aberrant miRNA expression is a common feature of many human diseases. In addition, miRNAs are involved in drug response. For example, the changes in miRNA expression in cancer cells are associated with resistance to anticancer drugs [89], and the underlying mechanism involves the fact that drug transporters (e.g., MDR1/P-glycoprotein, breast cancer resistance protein (BCRP/ABCG2), and multidrug resistance-associated protein 1 (MRP1)) are regulated by miRNAs [90–92]. Furthermore, miRNA expression is affected by chemicals, drugs, and steroid hormones, although these changes are likely smaller than those in mRNA expression. The miRNA manipulation therapy described above would result in larger changes in miRNA expression. miRNAs could be utilized to selectively modulate drug-metabolizing enzymes, drug transporters, and nuclear receptors toward optimal drug responses in pharmacotherapy.

19.11 CONCLUSIONS

There is considerable interindividual variability in the expression and activity of P450s, which consequently results in variability in drug response and toxicity. To understand the reasons behind this phenomenon, considerable effort has been put forth to uncover the mechanisms by which

P450s are transcriptionally and epigenetically regulated. Currently, miRNAs can be recognized as critical regulators of P450s to control pharmacological and toxicological outcomes. Robust studies of miRNA-related polymorphisms will provide a better understanding of interindividual variability in drug response and xenobiotic toxicity. In-depth understanding will be useful for individualized medicine. Future *in vivo* studies on the effects of changes in miRNA expression or function on drug metabolism and pharmacokinetics will offer valuable information for pharmacotherapy.

GLOSSARY

Noncoding RNA a biologically functional RNA actively transcribed from a gene that contains no open reading frame.

miRISC an RNA-induced silencing complex that contains mature miRNA and guides its inhibitory function to the target mRNA.

Argonaute 2 a protein that binds to small RNAs and is a component of RISC. In mammals, there are four Ago proteins, Ago1–4, which function in translational repression; only Ago2 has slicer activity.

Dicer an endoribonuclease that cleaves pre-miRNAs into 20–25-nucleotide, double-stranded miRNAs.

Single-nucleotide polymorphism a single-nucleotide base pair that varies between individuals. SNPs occur approximately once every 100–300 bp in the human genome and constitute an immense source of heterogeneity.

Ortholog a corresponding gene in different species that has descended from the same ancestral gene.

Paralog a gene that is derived from the same ancestral gene but reside in different locations in the same genome.

Cytochrome P450s the human cytochrome P450 superfamily, which comprises 57 genes. P450 sequences that display greater than 40% amino acid identity are classified in the same family; sequences that have greater than 55% identity are classified in the same subfamily. Members of CYP1–3 subfamilies are involved in the metabolism of xenobiotics, including drugs.

Xenobiotic a foreign chemical, which can be manufactured or natural, such as a drug, an industrial chemical, a pollutant, a pyrolysis product in cooked food, an alkaloid, or a secondary plant metabolite.

ABBREVIATIONS

AGTR	angiotensin receptor 1
Ago2	argonaute 2
AhR	aryl hydrocarbon receptor
ARNT	aryl hydrocarbon receptor nuclear translocator
AsO	antisense oligonucleotide
CYP	cytochrome P450
DHFR	dihydrofolate reductase
EET	epoxyeicosatrienoic acid
ER	estrogen receptor
FGF20	fibroblast growth factor 20
HIF-1α	hypoxia inducible factor 1α
MDR1	multidrug resistance 1
miRNA	microRNA
MRE	microRNA recognition element
NNK	4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone
PAHs	polycyclic aromatic hydrocarbons
PANK	pantothenate kinase
PCR-RFLP	polymerase chain reaction–restriction fragment-length polymorphism
PGC1β	peroxisome proliferator-activated receptor γ coactivator 1β
PARα	peroxisome proliferator-activated receptor α
PXR	pregnane X receptor
Pre-miRNA	precursor miRNA
Pri-miRNA	primary miRNA
RISC	RNA-induced silencing complex
SNP	single-nucleotide polymorphism
SULT	sulfotransferase
TRBP	TAR RNA binding protein
UTR	untranslated region
VDR	vitamin D receptor

20.1 OVERVIEW

Interindividual variability in drug response represents a major problem for both drug development and clinical practice. Adverse drug reactions (ADRs) are defined as "an appreciably harmful or unpleasant reaction, resulting from an intervention related to the use of a medicinal product; adverse effects usually predict hazard from future administration and warrant prevention, or specific treatment, or alteration of the dosage regimen, or withdrawal of the product" [1].

20.1.1 Classification

ADRs were originally classified by Rawlins and Thompson into two basic types: A and B (Table 20.1) [2]. Type A (or augmented) reactions are predictable, usually dose-dependent, and based on an exaggerated response to the known primary and/or secondary pharmacological action(s) of the drug. This is illustrated by bleeding episodes with warfarin therapy or hyperkalemia with potassium-sparing diuretics. Type B (or bizarre) reactions are unpredictable aberrant effects that are not expected from the known pharmacological action(s) of the drug when given in the usual therapeutic doses. This includes anaphylaxis or cutaneous eruptions with penicillins. However, as our knowledge of adverse drug reactions increases, some of these type B reactions will become predictable. Over time, the type A and B classification of ADRs was expanded to include types C, D, and E reactions (Table 20.2) [3].

More recently, a new classification system for ADRs was developed based on dose relatedness, timing, and patient susceptibility (DoTS) (Table 20.3) [4]. This system incorporates not only the properties of the drug (pharmacology and dose), but also the characteristics of the reaction (time course and severity) and the properties of the individual patient (genetic, pathological, or other biological differences that confer susceptibility).

The Rawlins and Thompson classification suggested that all type B ADRs are dose-independent, but this is not the case, as illustrated by type IV hypersensitivity reactions and desensitization using increasing dosages of antigen in cephalosporin allergies [5,6]. According to the DoTS classification, dose relatedness should be divided into reactions that occur at supratherapeutic doses (toxic effects), reactions that occur at standard therapeutic doses (collateral effects), and reactions that occur at subtherapeutic doses in susceptible patients (hypersusceptibility effects). For the latter, in particular, genetic

TABLE 20.1 Clinical Features and Classification of Type A and B Drug Reactions

Features	Type A	Type B
Pharmacology	Augmented	Bizarre
Predictable	Yes	No
Dose-dependent	Yes	No
Morbidity	High	Low
Mortality	Low	High

TABLE 20.2 Expanded Adverse Drug Reactions Classification

Adverse Drug Reactions	Definition	Examples
Type C	Continuing	Osteonecrosis of the jaw with bisphosphonates
Type D	Delayed	Leucopenia 6 weeks after lomustine dose
Type E	End-of-use	Insomnia, anxiety, and perceptual disturbances following withdrawal of benzodiazepines

TABLE 20.3 DoTS Classification for ADRs

	Variable	Classification
Do	Dose relatedness	Supratherapeutic Standard therapeutic Subtherapeutic
T	Timing	Time-independent Time-dependent
S	Susceptibility	Age Gender Genetics Pathology Physiology Environmental

factors may be important. Timing of ADRs is divided into time-independent and time-dependent. Time-independent reactions can happen at any time during the treatment course, but typically occur when the concentration of the drug at the site of action changes (e.g., renal failure) or when the pharmacological response to the drug is altered without a change in concentration (e.g., digoxin and hypokalemia). Time-dependent reactions are further subdivided into six subtypes: rapid, first dose, early, intermediate, late, and delayed (Table 20.4) [4].

TABLE 20.4 Subtype Classification of Time-Dependent Subtypes in DoTS Classification of ADRs

Subtype	Features	Examples
Rapid	Occurs when drug is administered too rapidly	Red-man syndrome with vancomycin
First dose	Occurs after first dose of treatment course	Hypotension after first dose of angiotensin-converting enzyme inhibitor (ACEi)
Early	Occurs early then abates with further treatment	Nitrate-induced headache
Intermediate	Occurs after some delay	Neutropenia with carbimazole
Late	Increased occurrence with recurrent or continued exposure	Adverse effects of corticosteroids
Delayed	Observed some time after exposure even if drug withdrawn before reaction occurs	Teratogenesis associated with thalidomide

Neither the Rawlins and Thompson nor the DoTS classification system is perfect, but both serve as important guidance for pharmacovigilance in clinical practice and drug regulation while providing important insights for future diagnosis, management, and prevention of ADRs.

20.1.2 The Burden of ADRs

ADRs are a major cause of morbidity, mortality, and increased healthcare costs. A study of almost 19,000 admissions at two National Health Service (NHS) hospitals in the United Kingdom found that 6.5% were related to an ADR [7]. Furthermore, of 3695 inpatient episodes occurring across 12 wards over a 6-month period, ADRs were seen in almost 15% and caused an increase in length of stay by an average of 0.25 days per patient admission [8]. Clearly, this places a significant financial burden on any healthcare system; in the NHS, a conservative figure of the financial burden of ADRs in adults is in the region of £637 million per annum [8]. In the United States, a meta-analysis of 39 prospective studies showed that 6.7% of hospital inpatients suffer serious ADRs, resulting in a mortality estimate of 100,000 U.S. deaths per year [9]. Similar results from a Swedish study showed that ADRs were the seventh most common cause of fatality [10].

A meta-analysis of 102 studies in children identified incidence rates for ADRs causing hospital admission to be 0.4–10.3% of all children (pooled estimate of 2.9% (2.6%, 3.1%)) and 0.6–16.8% of all children exposed to a drug during a hospital stay [11]. In accordance with these data, a prospective study of 8345 patient episodes in a large tertiary children's hospital estimated an incidence rate of 2.9% (95% CI 2.5, 3.3). Most of those serious enough to require hospital admission resulted from hospital-based prescribing, of which over a fifth may have been avoidable [12].

20.1.3 Predisposition to Adverse Drug Reactions

Predisposition, and thereby susceptibility, to ADRs can be due to many factors, including age, gender, genetic variation, pathology, physiological variation, and environmental factors (Table 20.5). It is therefore important to evaluate ADRs on a case-by-case basis and evaluate the role of both environmental and genetic factors. It is difficult to estimate the quantitative contribution of genetic factors to ADRs, which is likely to vary among drugs.

20.1.3.1 Twin Studies

Twin studies are a valuable tool to assess the relative contribution of genetic and environmental factors to variation in complex phenotypes, including drug response. Twin studies compare the similarity of a trait between monozygotic (MZ) twins who share 100% genetic identity and that of dizygotic (DZ) twins who on average share only 50% of the genome. It can be assumed that twins are raised in identical environments; therefore, any greater similarity of a trait shared between MZ twins compared to DZ twins can be attributed to genetics.

One of the first twin studies to identify a pharmacogenetic phenotype for ADR involved the antituberculosis (TB) drug isoniazid. In a study comparing metabolism between five pairs of MZ and DZ twins, investigators showed that the metabolism of isoniazid was far less variable in the former than in the latter [13]. This was later confirmed to be due, at least in part, to two distinct acetylation phenotypes (slow and rapid) that are determined by polymorphisms in the

TABLE 20.5 Sources of Altered Susceptibility to ADRs

Susceptibility Variable	Examples
Age	Increased susceptibility to hepatotoxicity with flucloxacillin[a]
Gender	Increased frequency of cutaneous adverse reactions among females[b]
Genetics	Azathioprine-induced myelosuppression in patients with significantly reduced thiopurine methyltransferase (TPMT) activity[c]
Pathology	Increased risk of lithium toxicity in patients with renal failure[d]
Physiology	Increased antiepileptic clearance among pregnant women with epilepsy associated with increased seizures[e]
Environmental factors	Consumption of grapefruit juice can affect bioavailability of numerous medications metabolized by CYP3A4 or transported by OATP[f]

N-acetyltransferase gene [14]. We now know that individuals who are "slow acetylators" are at greater risk of toxicity with compounds such as sulphonamides and aromatic amine carcinogens, and with isoniazid, which leads to hepatic toxicity and peripheral neuropathy [15–17]. Twin studies with other drugs, including antipyrine, phenytoin, halothane, and phenylbutazone have all shown that genetic factors are the main determinants of interindividual variation in metabolism [18]. However, in the majority of cases, it is likely that variability is multigenetic in origin and thus poses challenges in developing predictive tests [19].

20.2 PHASE I METABOLISM

20.2.1 P450 Phenotypes

It is likely that CYP450 polymorphisms have the greatest impact on type A ADRs where a single gene product predominantly determines drug clearance and consequently toxicological response. Polymorphisms affecting most of the genes encoding cytochrome P450 enzymes have been described. Variability in enzyme expression, or alteration in substrate specificity, may lead to interindividual variability in drug metabolism, which in turn affects drug plasma levels and thus susceptibility to adverse events. Poor enzyme activity may result in toxic drug accumulation, just as ultrarapid metabolism may cause rapid accumulation of active and, in some cases, more reactive metabolites. The genotype–phenotype correlation can be translated into four major phenotypes (Table 20.6).

20.2.1.1 CYP2D6

By far, the most intensively studied CYP450 gene is CYP2D6, which is responsible for the metabolism of 25% of all drugs [22]. To date, more than 70 variant alleles and over 130 genetic variants at the CYP2D6 locus have been described [23]. As a result of one or more point mutations, gene deletions, or multiplications, the resultant mutations can either have no effect on enzyme activity or can code for enzymes with decreased/absent activity (e.g., _CYP2D6*10_) or increased activity (e.g., _CYP2D6*2xN_) [20]. Absent or decreased CYP2D6 activity can lead to ADRs through either reduced first-pass metabolism, accumulation of the drug following reduced metabolism, or rerouting of metabolism. Similarly, increased activity may lead to ADRs through increased formation of active metabolites.

β-Blockers

Metoprolol undergoes extensive hepatic first-pass metabolism [24] with CYP2D6 the major enzyme involved [25,26]. Carriers of the poor metabolizer (PM) phenotype display significant increases in the bioavailability and half-life of the drug, with consequent increases in both peak and steady-state concentrations: metoprolol elimination half-life increases from 2.8 h in extensive metabolizers (EM) to approximately 7.5 h in poor metabolizers [26]. Furthermore, median dose-corrected plasma concentrations of metoprolol have been shown to be 6.2- and 3.9-fold higher in individuals carrying the PM or intermediate metabolizer (IM) phenotypes, respectively, than in EMs [27]. An increased risk of toxicity after metoprolol administration has been demonstrated, with PMs reported to have a 5-fold higher risk of ADRs [28]. Some prospective studies in hypertension [29] and heart failure [30], however, have failed to show an association between CYP2D6 metabolizer status and the occurrence of ADRs associated with metoprolol. However, these studies contained only small numbers of PMs (4 and 8, respectively) and must therefore be interpreted with caution.

CYP2D6 is also involved in the metabolism of other β-blockers, and the higher risk of toxicity in PMs has been demonstrated after administration of timolol (more pronounced bradycardia) [31] and carvedilol (reduction of

TABLE 20.6 Genotype–Phenotype Correlation of Cytochrome P450 Drug-Metabolizing Enzymes

Metabolizer Phenotype	Defect	Frequency	Consequence	Plasma Drug Level	Mechanism	Individualized Therapy
Poor (PM)	Carrying two defective alleles	5–10% [20,21][a]	Completely lack enzyme activity	Toxic	Creates unstable enzymes or amino acid changes leading to reduced substrate binding	Decrease dose to decrease toxicity
Intermediate (IM)	Heterozygous for a defective allele	[10–15]	Decreased enzyme activity	High		Standard dosing
Extensive (EM)	Carrying two functional alleles	75–85%	Proportionally increased amount of enzyme expressed in relation to number of gene copies. Promoter region and regulatory elements controlling gene transcription are duplicated	Normal	Increased enzyme expression with increased production of active metabolite	Standard dosing
Ultrarapid (URM)	Carrying >2 active gene copies (e.g., CYP2D6) Gain-of-function polymorphism (e.g., *CYP2C19*17*)	1–10% [20,21]		Low		Increase dose to increase efficacy

systolic blood pressure) [32]. Although known perturbations in PK parameters caused by PM status affect plasma concentrations of metoprolol and carvedilol, and hence can reasonably be assumed to result in greater adverse responses, larger, long-term prospective studies are required. These should include greater numbers of PMs in order to fully characterize whether this association is clinically significant.

Codeine

In contrast, ultrarapid metabolizers are at higher risk of codeine ADRs as a result of greater O-demethylation to codeine's active metabolite, morphine. The UM phenotype is associated with 50% greater plasma morphine concentrations than are EM phenotypes [33]. In February 2013, the U.S. food and drug administration (FDA) introduced a new Boxed Warning and Contraindication to the drug label of codeine-containing products [34]. This relates to the reporting of three fatalities and one life-threatening case of respiratory depression in children with the UM phenotype who were given codeine following tonsillectomy or adenoidectomy [35,36]. This triggered a European review of the safety of codeine-containing medicines in children. As a result, the MHRA issued a safety update in July 2013 stating that codeine is now contraindicated in children under 18 undergoing tonsillectomy or adenoidectomy for the treatment of obstructive sleep apnea. Codeine use is now restricted to children over the age of 12 for short-lived moderate pain unrelieved by other painkillers [37].

The latest developments in the restriction of codeine use followed a case report in 2006 that detailed the death of a neonate following the use of codeine for episiotomy pain following childbirth by the mother, who had the UM phenotype. After the mother's use of codeine (30 mg) and acetaminophen (500 mg) two tablets every 12 h (reduced by 50% on day two because of constipation), the infant displayed initial lethargy and poor breastfeeding, but by day 12 his skin was grey and he died on day 13 as a result of opioid overdose [38]. His postmortem blood morphine level was 70 ng/mL. The typical serum concentration in neonates breastfed by mothers taking regular codeine is usually 0–2.2 ng/mL [39]. This has led to safety warnings about the use of codeine in breast-feeding mothers by many regulatory authorities; however, regulatory bodies have not recommended genetic testing for codeine prescribing, although they do advise close monitoring, particularly in high-risk populations.

20.2.1.2 CYP2C9

Phenytoin

Phenytoin is the most widely prescribed antiepileptic drug in the U.S., accounting for 52% of prescriptions [40]. It has a narrow therapeutic index and shows wide interindividual variation. It is therefore difficult to administer effectively, requiring therapeutic drug monitoring. Phenytoin is metabolized to a mixture of (*R*) and (*S*) stereoisomers of the inactive compound 5-(4′-hydroxyphenyl)-5-phenylhydantoin (p-HPPH) by CYP2C9 and CYP2C19. CYP2C9 accounts for up to 90% of the metabolism of PHT [41]. Numerous previous studies demonstrated that the presence of *CYP2C9*2* and **3* alleles result in reduced *in vivo* phenytoin metabolism and reduced elimination, with an increase in drug concentrations necessitating the use of lower doses in patients [42–45]. In a recent candidate gene study [46] involving 182 Caucasians with epilepsy, 49 reported ADRs that were significantly associated with the presence of *CYP2C9*2* and **3* alleles. The association was replicated in a further 817 epilepsy patients. However, phenotypic data was collected retrospectively and therefore a number of confounding variables, including drug–drug interactions and compliance, may have led to misclassification. In another study of 281 epilepsy patients, the *CYP2C9*3* allele showed a significant association with maximum phenytoin dose but did not correlate with ADRs [47]. Interestingly, in a small study of 19 epileptic patients with the *CYP2C9*2* and **3* variants treated with phenytoin for over one year, there was significantly reduced cerebellar white matter volume in the variant group compared with demographically matched wild-type controls [48]. The relevance of this is unclear. Large prospective studies with adequate adjustment for confounding are required to assess the contribution of CYP2C9 polymorphisms and the risk of ADRs with phenytoin.

20.2.1.3 Other CYP450 Enzymes

Tardive Dyskinesia and Antipsychotics

Polymorphisms affecting response to antipsychotic medications are an example of where it has been difficult to replicate initial positive findings. There is wide variability in terms of response and tolerability with both typical and atypical antipsychotic drugs. Approximately 40% of antipsychotics are major substrates of CYP2D6, 23% are substrates of CYP3A4, and 18% are substrates of CYP1A2 [49]. This provides a plausible biological rationale for potentially explaining the degree of variability in response. However, a recent meta-analysis failed to show a significant association between tardive dyskinesia and CYP2D6 or CYP1A2 overall [50]. Still, restricting the analysis to prospective studies revealed a significant association between tardive dyskinesia and CYP2D6 in those who carried either two copies (OR = 2.08, 95% CI 1.21–3.57) or one copy (OR = 1.83, 95% CI 1.09–3.08) of the variant alleles when compared with the wild-type. In a large study of 100 patients taking psychotropic medications, Chou and colleagues [51] identified an increased risk of ADRs in PMs associated with prolonged hospital stay and greater treatment cost. Furthermore, a study of 85 patients with schizophrenia showed that patients with the C/C genotype for *CYP1A2*1F* are at significantly increased risk of tardive dyskinesia induced by typical antipsychotics, compared with those who are heterozygous or homozygous for the *CYP1A2*A* allele ($p = 0.0007$) [52]. However, Schulze and colleagues [53] failed to replicate this association in 119 German patients with schizophrenia. Patient heterogeneity and poor phenotyping may explain the disparity to a degree; this is a problem that affects all genetic case-control association studies.

To date, no large randomized control trials (RCTs) have evaluated whether genotyping can successfully reduce the frequency of ADRs associated with antipsychotic medication and the consequent treatment interruption or withdrawal—which has a large impact on outcome. This information is essential for cost-effectiveness analysis and implementation in clinical practice, but of course large RCTs are expensive, particularly given how infrequent some polymorphisms are.

20.3 PHASE II METABOLISM

20.3.1 Thiopurines

Thiopurine S-Methyltransferase (TPMT) catalyzes the S-methylation of thiopurine drugs, including azathioprine (AZA) and 6-mercaptopurine (6-MP). Both are prodrugs metabolized via a series of steps to the 6-thioguanines. These are then incorporated into DNA and RNA, causing immunosuppression. AZA and 6-MP are suitable treatments for a range of immune diseases including rheumatoid arthritis, inflammatory bowel disease, and pediatric acute lymphoblastic leukemia (ALL).

20.3.1.1 Adverse Effects of Thiopurines

A serious adverse effect of both AZA and 6-MP is severe bone marrow depression [54,55]. This results from deficiency of the TPMT enzyme and leads to the increased formation of a cytotoxic 6-thioguanosine nucleotide metabolite via an alternative metabolism pathway. In addition to bone marrow toxicity, hepatitis and pancreatitis are among the most common ADRs associated with thiopurine use, leading to dose reduction or discontinuation in 9–28% of patients [56]. ADRs can occur with the thiopurines at both ends of the enzymic-activity spectrum. Those with low TPMT activity effectively receive an overdose with standard dosing, and hence are 30–40% more likely to develop an ADR. Conversely, very high TPMT activity increases the risk of hepatotoxicity resulting from increased production of methylated thiopurine metabolites [57,58].

20.3.1.2 TPMT Phenotype

The TPMT phenotype test quantifies the level of enzyme activity in red blood cells. Phenotyping is considered to be more reliable for the detection of myelosuppression risk [59,60]. However, the retrospective nature of the relevant studies may not have provided a true measure of ADRs. Recent reports are emerging that suggest genotyping to be the most reliable test, particularly in heterozygotes [61].

20.3.1.3 TPMT Genotype

Approximately 86–97% of patients have the *TPMT*1/*1* (wild-type) genotype, conferring normal TPMT enzyme activity. *TPMT*3C* contains A719G on exon 10 [62], *TPMT*3A* is characterized by a double mutant allele (G460A on exon 7 and A719G on exon 10) [62–66], and *TPMT*2* is a G238C transition on exon 5 [63]. Together these polymorphisms account for 80–95% of deficient TPMT activity in Caucasians, African-Americans, and Asians. Approximately 3–14% of patients are heterozygous for the *TPMT* genotype and possess one variant allele [67]. Deficiency is associated with homozygosity for these alleles. The population prevalence for deficiency is low (approximately 1 in 178 to 1 in 3736 patients) [67], but these patients are at greatest risk for severe myelosuppression and associated life-threatening complications, including sepsis. It has therefore been suggested that dose reduction or alternative drug selection may be appropriate in heterozygotes and homozygotes, respectively.

In the largest prospective study to use full-dose azathioprine (2 mg/kg) without dose adjustment in patients with IBD, Ansari and colleagues found that the heterozygous *TPMT* genotype strongly predicted ADRs (79% heterozygous versus 35% wild-type TPMT, $p<0.001$), especially for gastric intolerance and myelosuppression [68].

Currently there are eight genotype tests available and no single gold standard. Systematic review of all methods in a nonspecific population concluded that genotype tests overall have lower sensitivity but greater positive predictive value than the TPMT phenotype test, but a wide range of sensitivity and specificity [69]. The *TPMT* genotype test cannot be considered the gold standard for identification of myelosuppression risk because the genotype is not solely responsible for this risk and the test itself is designed to detect a limited number of mutations. In clinical practice, it is estimated that only approximately 25% of cases of leukopenia in patients with IBD treated with thiopurines are related to the presence of a polymorphism [70].

20.3.1.4 Perspectives of Professional and Regulatory Bodies

The FDA and prescribing information for AZA and 6-MP recommend *TPMT* genotyping or phenotyping prior to initiating therapy to improve identification of at-risk patients [71]. The American College of Gastroenterology treatment guidelines prefer *TPMT* phenotyping over genotyping because phenotyping reports a quantitative level of TPMT enzyme activity [72]. In the United Kingdom, phenotyping is the preferred method for routine TPMT screening. However, the British Society of Gastroenterology guidelines do not require either *TPMT* genotyping or *TPMT* phenotyping prior to initiating thiopurine therapy because the use of AZA has been shown to be relatively safe in patients with IBD, and the occurrence of leucopenia can be handled through regular blood count monitoring [73,74].

20.3.1.5 Cost-Effectiveness

Six economic evaluations conducted in rheumatological disorders and inflammatory bowel disease have concluded that pretreatment TPMT testing for AZA is a cost-effective use of healthcare resources [75–80]. Genotype-directed dosing schedules compared favorably with other dosing schedules, with pretreatment genotyping costing $579 per life-year saved for a 30-year-old and $1364 per life-year saved for a 60-year-old [75]. The studies reporting these results were retrospective modeling studies that synthesized existing clinical and cost data supplemented by expert opinion where necessary. However, a recent cost-effectiveness analysis in children with acute lymphoblastic leukemia (ALL) reported that screening for TPMT mutations using either genotype or enzymatic laboratory tests prior to administration of 6-MP in pediatric ALL patients did not demonstrate any survival benefit and was therefore not cost-effective. Incremental costs per child (95% confidence interval) were $277 and $298 for the genotyping and phenotyping strategies, respectively, compared to weight-based dosing [81].

20.3.2 Cisplatin

TPMT deficiency related genotypes have also been identified as a risk factor for drug-induced ototoxicity (hearing loss) in children treated with cisplatin for a range of neoplasms [82]. Indeed, in this study 26 of 162 children carried one or more *TPMT* variants, and of these 26, 96% [23] suffered from the most severe ototoxicity. This finding was recently replicated in 155 children and led to a revision of the cisplatin drug label by the FDA to include information relating to *TPMT* pharmacogenetics and ototoxicity [83,84].

20.3.3 Isoniazid

Isoniazid is among the first line antituberculosis (TB) drugs, commonly given in combination with rifampicin and pyrazinamide as RIFATER®. Metabolism and excretion of isoniazid is principally by N-acetyltransferases (NAT) 2-mediated acetylation and CYP2E1.

NATs catalyze the biotransformation of aromatic amines and hydrazines by transferring the acetyl group of acetyl coenzyme A to the free amino group of the parent compound. They are found in two forms in humans: NAT1 and NAT2. NAT1 is ubiquitous, whereas NAT2 expression is generally restricted to the liver and intestine. NAT2 is highly polymorphic, with several mutations affecting its activity. The mutations result in three main acetylator phenotypes: (1) slow acetylators resulting from amino acid changes include *NAT-2*5*, *NAT-2*6*, *NAT-2*7*, and *NAT-2*14* [85]; (2) homozygous alleles at all four loci produce the rapid acetylator phenotype, with heterozygotes referred to as intermediate metabolizers [85–88]; (3) NAT2-determined slow metabolizers acetylate isoniazid slower than fast metabolizers, resulting in the accumulation of toxic intermediates in the liver and leading to hepatotoxicity. This has been demonstrated in those with the slow acetylator phenotype [89], although there is some conflicting evidence [90].

Recently, rs1495741, a novel tag SNP in NAT2 was reported to confer high sensitivity for prediction of NAT2 acetylator phenotype in Europeans (MAF 23.9%) [91]. A subsequent study [92] determined the MAF of rs1495741 in the Taiwanese population to be higher—almost 50%—and associated with a 14-fold increased risk of hepatotoxicity following antiTB treatment (isoniazid, pyrazinamide, and ethambutol) in patients with the AA genotype of rs1495741 [92].

This increase in risk is sufficient enough that the FDA has included genotypic information on the drug label for RIFATER® that reads "Slow acetylation may lead to higher blood levels of the drug and thus an in increase in toxic reactions" [93].

20.3.4 Sulfamethoxazole

Prophylactic sulfamethoxazole (SMX) is commonly prescribed for the prevention of *Pneumocystis jirovecii* pneumonia (PJP) in patients with HIV/AIDS. SMX is metabolized and excreted via NAT1 and NAT2 acetylation and is associated with a delayed hypersensitivity reaction [94]. The frequency of hypersensitivity reactions is notably greater in HIV-positive individuals (30–50%) when compared to non-HIV positive controls (3%) [95,96]. It has been suggested that the NAT2 slow acetylator phenotype is a risk factor for the development of SMX hypersensitivity reactions [97]. One study found a higher frequency of slow acetylators in SMX-hypersensitive HIV-positive patients [98,99], but other studies have disputed this association [100–102]. Further study suggests that the discrepancy between N-acetylator phenotype and genotype in HIV-positive patients results from the presence of rare alleles [103].

20.3.5 Irinotecan

The topoisomerase I inhibitor irinotecan is approved globally for the treatment of metastatic colorectal cancer. It is principally metabolized to its active metabolite SN38 by CYP3A and esterases. Detoxification of SN-38 occurs by glucuronidation facilitated by uridine diphosphate glucuronosyltransferase 1A1 (UGT1A1). Failure of this mechanism, and hence increased circulating unconjugated SN-38, puts patients at increased risk of severe neutropenia. The uridine diphosphate glucuronosyltransferases (UGTs) are a superfamily of enzymes primarily located in the endoplasmic reticulum of cells involved in the detoxification of exogenous compounds. The *UGT1A* gene loci is found at chromosome 2q37 and encodes all enzyme isoforms by alternative splicing of a unique exon 1 to a common domain that contains exons 2–5.

Among the most characterized polymorphisms in genes of the *UGT1A* family is a TA tandem repeat polymorphism in the *UGT1A1* promoter region. Alleles with 7 TA repeats, known as *UGT1A1*28,* have significantly lower transcription rates than does the wild-type allele (6 repeats) [104]. In one of the first examples of regulators applying pharmacogenomic biomarker information to dosing guidelines on a drug label, the FDA in 2005 advised that individuals who are homozygous for the *UGT1A1*28* allele are at increased risk of neutropenia following initiation of treatment with irinotecan, and dose reduction should be considered [105].

Numerous studies have confirmed the risk of neutropenia and/or diarrhea in carriers of the *UGT1A1*28* allele [106–112]. A meta-analysis of 821 patients suggested that, while *UGT1A1*28* homozygosity is indeed a risk factor for neutropenia, the risk is increased further in **28/*28* patients receiving high-dose irinotecan. Neutropenia risk in individuals receiving low-dose irinotecan was not significantly different among those homozygous for the wild-type allele, while high-dose **28/*28* genotype patients were at significantly greater risk (odds ratio = 27.8 [4.0–195]) [113]. Moreover, a meta-analysis of 16 trials in Caucasians confirmed that genotyping for the *UGT1A1*28* polymorphism before treatment can tailor therapy and reduce toxicity.

Although toxicity variants are greatest in *UGT1A1*28* homozygotes, those bearing the heterozygous variant are also at risk. Recently, a small phase II study of UGT 1A1 polymorphism-guided dose reduction in patients with metastatic colorectal cancer treated with irinotecan and 5′-deoxy-5-fluorouridine showed that dose reduction based on the **28* genotype is effective and safe. In wild-type **1/*1* individuals (22.7%) versus those carrying one variant **28* (16.7%) allele, no significant differences in response rate were identified and toxicities of grade 3 or higher including neutropenia (9.0% versus 0%, respectively) and diarrhea (13.6% versus 0%, respectively) were prevented. Importantly, another recent meta-analysis concluded that an individual's response to irinotecan is unlikely to be affected by *UGT1A1*28* status [114].

20.3.6 Combined PKPD

20.3.6.1 Warfarin

Approved in 1954, warfarin is an effective and widely prescribed anticoagulant for the prevention of thromboembolism. The International Normalized Ratio (INR) monitors the degree of anticoagulation in patients treated with it. Despite its effectiveness, warfarin's narrow therapeutic window and unpredictable interindividual variability poses a significant challenge to prescribers, particularly given the consequences of supratherapeutic INR with bleeding rates varying from 0.75% per year to as high as 10% in some studies [115,116].

Warfarin consists of a racemic mixture of *R* and *S* enantiomers and displays stereoselective metabolism; *S* warfarin is approximately three to five times more potent than *R* warfarin [117]. CYP2C9 is the main enzyme involved in the metabolic elimination of S warfarin. Warfarin's anticoagulant effect is achieved via binding of the 4-hydroxycoumarin ring to vitamin K epoxide reductase (VKOR), preventing reduction of vitamin K epoxide to dihydrovitamin K [118], the necessary co-factor required for the gamma-glutamyl carboxylation of vitamin K-dependent clotting factors [119,120]. As such, warfarin represents an excellent paradigm for how both PK and PD-related genetic variability can affect drug efficacy and safety.

Pharmacokinetics

CYP2C9 is the main enzyme involved in the metabolic elimination of S warfarin. Normal enzyme function (wild-type) is denoted *CYP2C9*1*, with the two most common allelic variants, *CYP2C9*2* (p.R144C) and *CYP2C9*3* (p.I359L) causing reductions in enzyme activity of 30% and 80%, respectively [121,122]. There are racial differences in the prevalence of CYP2C9 alleles. Approximately 1% of Caucasians are homozygous for the **2* variant; 0.4% are homozygous for **3* and heterozygous carriers for *CYP2C9*2*, *CYP2C9*3*, and *CYP2C9*2/*3*—representing about 22%, 15%, and 1.4% of the population, respectively. The *CYP2C9*2* and *CYP2C9*3* alleles are much less prevalent among Asians and African-Americans. Alteration in CYP2C9 enzymatic activity is associated with greater bleeding risk per given dose in patients treated with warfarin.

Pharmacodynamics

In the liver, warfarin targets the vitamin K epoxide reductase complex subunit 1 encoded by the *VKORC1* gene located on chromosome 16p11.2. Ten common non-coding *VKORC1* SNPs have been identified and grouped into five major haplotypes (H1, H2, H7, H8, and H9) with greater than 5% frequency in European Americans [123]. These can then be divided into two distinct evolutionarily distant groups, designated A (comprising H1 and H2) and B (comprising H7, H8, and H9); these groupings have been shown to significantly affect warfarin dose requirements, with genotype AA being the most sensitive and requiring the lowest dose and BB associated with the lowest enzyme activity and hence requiring the highest dose [123,124].

Regarding warfarin dose determination, in the last decade, substantial progress has been made in our understanding of how genotypes affecting CYP2C9 and *VKORC1* determine dose requirements [121–123,125–131]. When combined with environmental factors, genotypes affecting both CYP2C9 and *VKORC1* can predict around 50% of interindividual dose variation [132–134]. The initial 3-month period following warfarin commencement is considered "high-risk," with a 10-fold higher risk of bleeding events as compared to subsequent months [135]. Consequently, a combined genetic and clinical information approach could be adopted to guide the initiation of warfarin therapy during this period.

Warfarin labeling has undergone important revisions in the last decade. In 2007 and again in 2010, the FDA revised the drug label to incorporate into dosing decisions consideration of genotypic variation in *CYP2C9* and *VKORC1*. This led to the development of pharmacogenetic prediction algorithms [132,136,137]. Data from individual groups can be limited by geographical restriction and small sample size. In the largest study to date, the International Warfarin Pharmacogenetics Consortium (IWPC) demonstrated that the pharmacogenetic algorithm was significantly superior to the clinical algorithm in predicting stable warfarin dose in subjects who required <21 mg weekly and >49 mg weekly [132]. The IWPC is made up of 22 research groups across 11 countries; its investigators pooled genotype and phenotype data from 5700 warfarin-treated patients to produce a geographically and ethnically diverse population for study. Numerous prospective randomized controlled trials performed in recent years comparing pharmacogenetic with clinical algorithms have consistently demonstrated the superiority of the former [138–142]. Indeed, Finkelman et al. [138] demonstrated that, although genetic tables (as recommended by the FDA) predict warfarin dose better than empiric dosing, formal pharmacogenetic algorithms are the most accurate.

Bleeding Risk

Genetic variation contributes to increased bleeding risk. In the U.S. Medco and the Mayo clinic showed that warfarin genotyping reduced hospitalization rates for bleeding and thromboembolism by 43% [139]. In those carrying *CYP2C9* variants, patients have been shown to be at increased risk of over-anticoagulation and bleeding during induction

[125,126]. A meta-analysis involving 2775 patients demonstrated that this bleeding risk is greater with variants compared to carriers of the wild-type [143]. Patients with the *CYP2C9*2* and *CYP2C9*3* alleles had lower mean daily warfarin dose requirements and a greater risk of bleeding. In a racially diverse cohort followed prospectively for two years after initiation of warfarin, the variant *CYP2C9* genotype was associated with an increased risk for major hemorrhage [144].

The *VKORC1*−1639A allele is associated with higher INR values and more time spent with an INR above the upper limit of the therapeutic range [124,137,145,146]. Despite this, and in contrast to CYP2C9 variants, the majority of studies involving *VKORC1* polymorphisms have not shown any significant association between genetic variation in *VKORC1* and bleeding risk [124,144,147]. A single case-control study demonstrated an association between carriers of at least one T allele and increased risk of bleeding (crude odds ratio = 1.7, 95% CI: 1.1–2.5) compared to individuals with the wild-type genotype [148].

The majority of pharmacogenetic studies of warfarin have been conducted in Caucasian populations; therefore, the ability to predict the risk of over-anticoagulation may not be consistent across race. There is also lower linkage disequilibrium and greater variation in the African-American genome compared with non-Africans [149]. Consequently, genetic variants that influence warfarin sensitivity in non-Caucasians may go undetected in most studies. Indeed, resequencing of the *VKORC1* gene for SNP discovery was initially limited to an entirely Caucasian population [123]. A recent GWAS study in African-American individuals identified a novel CYP2C polymorphism that exerted a clinically important effect independent of the *CYP2C9*2* and **3* polymorphisms; this should also be incorporated into future genetic dosing algorithms [150].

Whether pharmacogenetic testing for warfarin is cost-effective remains to be seen. Ongoing prospective, randomized trials are evaluating its clinical utility and will provide important data to inform cost-effectiveness analyses. In particular, cost-effectiveness may vary by population, which could mean that testing will be restricted to those at greatest risk of adverse outcomes of supratherapeutic INR—the elderly, for example.

20.4 TYPE B ADVERSE DRUG REACTIONS

20.4.1 Malignant Hyperthermia and Anesthesia

Malignant hyperthermia (MH) is a potentially fatal hypermetabolic reaction of skeletal muscle that can be triggered by the administration of depolarizing muscle relaxants and/or halogenated anesthetics (e.g., halothane, enflurane, isoflurane). A MH reaction is characterized by dysregulated myoplasmic calcium (Ca^{2+}) leading to tachycardia, muscle rigidity, rhabdomyolysis, increased oxidative/nitrosative stress, mitochondrial damage, acidosis, hypercapnia, renal failure, and ultimately death [151]. MH was originally described in 1960 in a case report of a man who had experienced the deaths of ten close family members due to anesthetic complications [152]. The prevalence of MH has been estimated at 1.1 per 100,000 surgical discharges where there was indication for anesthesia [153]. MH occurs more frequently in men and younger patients (median age 22) [153–155]. MH-related mortality was estimated at 0.0082 per 100,000 surgical inpatients in a U.S. population [153].

MH is associated with a high morbidity rate of 35%, including coma, cardiac dysfunction, and renal dysfunction, which emphasizes the importance of improved treatments and prevention in future [154]. Dantrolene is the treatment of choice for MH and has reduced mortality from 80% in the 1960s to less than 10% today. Its pharmacological action is not completely understood, but inhibition of the ryanodine receptor, the major Ca^{2+} release channel of skeletal muscle sarcoplasmic reticulum, is believed to be fundamental in decreasing intracellular calcium concentration [156].

Susceptibility to MH is inherited as an autosomal dominant trait with variable expression and incomplete penetrance. Its exact pathophysiological mechanism is not completely understood, but uncontrolled release of Ca^{2+} from skeletal muscle sarcoplasmic reticulum disturbs the excitation-contraction coupling (ECC) of normal muscle contraction, leading to hypercontracture and hypermetabolism [157]. The cause of dysfunctional Ca^{2+} regulation in MH is, in most cases, secondary to defects in the ryanodine receptor type 1 (RYR1) and/or the dihydropyridine-sensitive L-type voltage-dependent calcium channel (DHPR).

20.4.1.1 Diagnosis

Individuals with MH are phenotypically normal and will only manifest symptoms of MH when exposed to triggering anesthetic agents. In patients who have had a suspected episode of MH, confirmation of the diagnosis is crucial because the condition is dominantly inherited and could affect other family members. Currently, diagnosis is based on a combination of muscle contracture testing and molecular genetic screening [158].

Muscle Contracture Testing

The "gold standard" for diagnosis of MH is the muscle contracture test, of which two versions exist: the *in vitro* contracture test (IVCT) devised by the European Malignant Hyperthermia group (EMHG); and the caffeine-halothane contracture test (CHCT) devised by the North American Malignant Hyperthermia Group (NAMHG) [159,160]. The two tests differ in methodology but essentially involve a muscle tissue biopsy from the affected individual, exposure of the muscle fibers to halothane and caffeine, and then observation for a positive contractile response (Table 20.7) [158].

Despite these slight differences, the EMHG IVCT has a sensitivity of 99% and a specificity of 93.6%, while the NAMHG CHCT has a sensitivity of 97–98% and a specificity of 78–80% [161,162]. Both versions have very high sensitivity values because MH is a potentially fatal adverse reaction and anesthesiologists are more likely to accept false-positive results compared with false-negative results. Although the diagnostic gold standard, the muscle contracture test is invasive and expensive, and can only be done in specialized centers. Therefore, alternatives such as molecular genetic testing have been introduced.

Genotype Testing

Genetic testing for MH was introduced into clinical practice in 2005 [163]. More than 300 mutations have been identified with *RYR1*, although only 30 of these have sufficient evidence to be considered causal for MH [164]. Approximately 30% of patients with MH carry one of the 30 variants in *RYR1* that are known to be causal, while up to 70% of MH patients carry a *RYR1* DNA variant, whether causal or of unknown significance [165,166]. To determine if a variant is causally associated, it must be characterized through genetic and functional studies while satisfying all the requirements set out by the (EMHG) (http://www.emhg.org/documents/) (Table 20.8).

The other genetic association reported with MH is in *CACNA1S*, which encodes the alpha-1 subunit of the skeletal muscle DHPR and accounts for approximately 1% of cases of MH [167].

Genetic diagnosis of susceptibility to MH by analysis of *RYR1* and *CACNA1S* is difficult because of significant genetic heterogeneity and discordance between genotype and phenotype. No single dominant mutation is causal for MH, and the *RYR1* and *CACNA1S* genes are complex, comprising 106 exons and 46 exons, respectively [168,169]. The A1352G substitution in *RYR1* is associated with MH in Caucasian patients, but in individuals of African descent the polymorphic change appears to be neutral, suggesting that DNA mutation profiles may differ between human populations [170]. Adding further complexity is the varying prevalence of specific mutations in different populations. In the United Kingdom, the most common mutation is G2434R, whereas in Germany and France R163C is more commonly reported [171]. These findings highlight the importance of not only screening for mutations among different ethnicities, but also screening of large numbers of control patients to exclude nonsignificant mutations.

Currently, the major limitation of genetic screening for *RYR1* in the diagnosis of MH is that a negative result cannot exclude MH without further muscle contracture testing. Other limitations include low sensitivity (25%) and considerable inter- and intraindividual variation in phenotypic expression [172]. However, genetic testing does have a role in screening family members of patients who have been definitively clinically diagnosed with MH and where a causative mutation has been identified. This mutation is then screened for in-family members; if they are positive, they are regarded as MH susceptible without muscle contracture testing [158,173].

Another limitation of genetic testing is the significant variation in phenotype expression and penetrance in individuals who carry genetic mutations associated with MH, although mutations that occur in highly conserved regions of *RYR1* seem to be associated with a more severe MH phenotype [163,174]. The role of epigenetic factors and the effects of multiple mutations in a single *RYR1* gene remain unclear [175,176]. Until our understanding of the relationship between genotype and phenotype improves, the goal of genetic testing alone to diagnose MH in clinical practice remains distant.

20.4.2 Statins and Skeletal Muscle Toxicity

The 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA reductase) inhibitors (statins) prevent the

TABLE 20.7 Diagnostic Criteria for European and American Muscle Contracture Testing

	In Vitro Contracture Test (IVCT)	Caffeine-Halothane Contracture Test (CHCT)
MH susceptible	Positive response to both halothane and caffeine	Positive result for either halothane or caffeine
MH normal	Negative response to both halothane and caffeine	Negative response to both halothane and caffeine
MH equivocal	Positive response to either halothane or caffeine	Not applicable

TABLE 20.8 EMHG Criteria for Gene Mutations to be Used in Genetic Testing of MH Susceptibility

Genetic characterization	• Full description at DNA and protein level, considering evolutionary conservation and change in charge, polarity, or structure introduced by amino acid replacement • Co-segregation of mutation with disease in at least 2 pedigrees • Absence of sequence change from 100 control samples for exclusion of polymorphism
Functional characterization	• Recombinant *in vitro* expression on a defined background (e.g., expression of mutated RYR1 cDNA construct in cells that do not express RYR1) and measurement of Ca^{2+} release in response to RYR1-agonists • Alternatively, myotubes of RYR1-knockout mice can be used as recipients for expression of cDNA constructs

Assays of RYR1 function in *ex vivo* tissues	• Calcium measurement ligand-binding studies performed on tissues from MH patients with characterized RYR1 mutations:
	  • Myotubes
	  • Microsomal SR preparations from muscle biopsies
	  • Lymphoblasts
	• To avoid interference of other genetic factors, all assays based on cells taken from patients should be performed on samples from at least 2 independent patients with same mutation

biosynthesis of cholesterol, thereby lowering low-density lipoprotein cholesterol (LDL-C) and reducing cardiovascular events. Statins are generally well tolerated, and the incidence of ADRs is rare. However, safety concerns arose following the worldwide withdrawal in 2001 of cerivastatin because of an unacceptably high incidence of rhabdomyolysis. In general, muscle toxicity with statins ranges from myalgia (muscle pain without any elevation in creatine kinase (CK)) to rhabdomyolysis (severe muscle damage where the CK is >10 times the upper limit of normal) [177]. A systematic review of 20 RCTs in statin-treated patients versus placebo defined the incidence of rhabdomyolysis as 3 per 100,000 person-years in those taking simvastatin, lovastatin, atorvastatin, pravastatin, or fluvastatin [178]. Muscle toxicity inevitably affects compliance; 25–50% of patients with coronary artery disease (CAD) are noncompliant with a prescribed drug at 12 months [179]. Thus, although the incidence of rhabdomyolysis is low, other muscle symptoms, in particular muscle pain without a rise in CPK, may be more common, and likely to lead to drug discontinuations.

Although the exact cellular mechanism underlying the myopathic effect of statins has not been fully elucidated, it is clear that it is dose-dependent [180] and increases with increasing blood concentrations [181]. SLCO1B1 is an organic anion transporting polypeptide exclusively localized to the hepatic basolateral membrane; it is a key mechanism for hepatic uptake of statins. Functional variation of SLCO1B1 has been implicated in statin-induced myopathy and comprises 5 haplotypes—*1a wild-type, *1b usual transport activity, *5 (c.521T>C alone), *15 (combined c.521T>C and c.388A>G), and *17—all with reduced transport activity. Reduced transport ultimately leads to increased circulating statin concentrations and, indeed, increased AUCs have been seen in carriers of at least one copy of the *5 or *15 allele taking atorvastatin [182], rosuvastatin [182], pravastatin [183], and simvastatin [184].

In particular, variation involving the *5 allele (rs4149056), has been associated with higher rates of statin intolerance [185–187] and high risk of developing statin myopathy as determined by GWAS [188]. The risk of statin-induced myopathy is additive, dependent on the number of *5 alleles carried. The incidence in those with no, one, or two *5 alleles has been shown to be 20%, 27%, and 50%, respectively [187]. The greatest risk appears to occur with simvastatin. Some studies failed to show a comparable risk with atorvastatin [188,189], pravastatin [187], or rosuvastatin [190], but the small sample size of these studies restricts the validity of the findings. A recent large real-world study of 288 Caucasian individuals treated with atorvastatin or rosuvastatin identified a 45-fold interindividual variability in plasma levels in those taking the same dose, which is almost entirely attributable to genetic variation. Individuals were genotyped for common uptake and efflux transporter polymorphisms along with drug metabolism polymorphisms. Measurement of 4B-hydroxycholesterol concentration served as a marker of CYP3A4; lathosterol concentration, as a measure of statin-mediated inhibition of de novo cholesterol synthesis. Ninety percent of rosuvastatin variability is attributable to the reduced-function transporter polymorphisms in SLCO1B1 and ABCG2; for atorvastatin, this is divided between SLCO1B1 and CYP3A4. In addition, retrospective analysis of 579 patients taking statins revealed that almost 50% of those taking the highest doses have concentrations above the 90th percentile, suggesting the appearance of a high-risk group. The authors propose a dosing algorithm for statin prescribing that incorporates genomic and clinical variables in order to reduce the risk of statin myopathy [191].

More recently, a breakthrough study reported that levels of expression quantitative loci (eQTL) varied between simvastatin-exposed and non-simvastatin-exposed controls *in vitro*. The most significant eQTL with simvastatin exposure was associated with the gene glycine amidinotransferase (*GATM*), which encodes the enzyme for the rate-limiting step of creatine synthesis. Variation in this locus was demonstrated to affect cholesterol synthesis and metabolism and was significantly associated with statin-induced myopathy. The authors hypothesize that GATM may represent the link between statin-induced myopathy and cellular cholesterol homeostasis and energy metabolism [192].

20.4.3 Drug-Induced Skin Injury

Drug-induced skin injury (DISI) is common and has diverse clinical manifestations ranging from mild inflammation, such as maculopapular exanthema (MPE), to severe life-threatening reactions that include Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), acute generalized exanthematous pustulosis (AGEP), and hypersensitivity syndrome (HSS) (Table 20.9) [193]. DISI reactions are estimated to account for 5–15% of all ADRs [194]. The strongest genetic associations with ADRs have been reported with human leukocyte antigens (HLA) (Table 20.10). HLA alleles are encoded by the major histocompatibility complex (MHC) on chromosome 6 and play an integral role in immune response to antigens. It has been proposed that specific HLA molecules present drug or drug metabolites to T cells, which trigger the immune system and lead to a hypersensitive reaction [195]. The exact mechanism by which this occurs is not definitively known and may vary with different drugs. Several hypotheses have been put forward that are outside the scope of this chapter. Readers are referred to excellent reviews for further information [196,197].

20.4.3.1 *Abacavir Hypersensitivity*

Abacavir is a nucleoside reverse transcriptase inhibitor prescribed for the treatment of human immunodeficiency virus (HIV) infection [198]. Approximately 5% of patients experience abacavir hypersensitivity syndrome (AHS), with clinical features similar to HSS. It usually presents within 6 weeks of initiation of abacavir, which necessitates immediate cessation of therapy. Re-exposure of these patients to abacavir leads to rapid reappearance of symptoms and the potential to induce more severe symptoms [199]. The clinical features of AHS and the discovery of CD8+ T-cell response in skin biopsies of abacavir patch test-positive patients have provided evidence for an immune-based etiology in AHS [200]. Genetic susceptibility is suggested by familial disposition to AHS, reduced risk in black ethnicities, and the observation that only a minority of patients develop hypersensitivity within six weeks, while those who do not remain at low risk despite long-term therapy [201,202].

AHS was first reported to be significantly associated with *HLA-B*57:01* in an Australian cohort [203]. In this cohort, 14 out of 18 (78%) AHS patients were positive for HLA-*B*57:01* compared with 4/167 (2%) of abacavir-tolerant cases (OR = 117, $p < 0.0001$, 95% CI 29–481). Screening

TABLE 20.9 Phenotype Definitions in Drug-Induced Skin Injury

Phenotype	Clinical Features
Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN)	Skin detachment: 1–10% in SJS 10–30% in overlap syndrome >30% in TEN Severe erosions of mucous membranes—may be hemorrhagic Systemic involvement: Fever Deranged liver function tests Lymphopenia Intestinal manifestations Pulmonary manifestations
Hypersensitivity Syndrome (HSS); also known as drug-induced hypersensitivity syndrome (DIHS); drug reaction with eosinophilia and systemic symptoms (DRESS); drug-induced delayed multiorgan hypersensitivity syndrome	Fever (typically >38°C) Exanthema Lymphadenopathy Internal organ involvement Eosinophilia Atypical lymphocytes Lymphopenia Thrombocytopenia
Acute generalized exanthematous pustulosis (AGEP)	Acute widespread edematous erythema followed by sterile pustular eruption Pustules initially located in neck, groin, and axillae; later become widely disseminated Fever (>38°C) Neutrophilia +/– mild eosinophilia

for *HLA-B*57:01* was reported to have a positive predictive value (PPV) of 100% and a negative predictive value (NPV) of 97%. The association was subsequently replicated in populations from North America and the United Kingdom [204,205].

Once the association between *HLA-B*57:01* and AHS was confirmed, subsequent research efforts focused on translating the association into a clinically applicable test for identification of susceptible individuals. Simple tests for *HLA-B*57:01* were developed and prospective screening has significantly reduced the incidence of AHS from 8% to less than 1% across multiple populations and ethnicities including the United Kingdom, France, and Australia [206–210]. The PREDICT-1 prospective controlled trial randomized 1956 patients from 19 countries into *HLA-B*57:01* screening or a standard-care approach of abacavir therapy without screening. The results were that the incidence of AHS in the prospective screening group was 3.4% compared with 7.8% in the control group ($p<0.001$), confirming the clinical utility of pretreatment *HLA-B*57:01* testing in abacavir treatment [211].

Three studies across different populations addressed the issue of cost-effectiveness of screening for *HLA-B*57:01* prior to initiation of abacavir therapy [205,212,213]. *HLA-B*57:01* screening before abacavir therapy was concluded to be cost-effective but dependent on the costs and efficacy of alternative therapies, such as tenofovir-containing antiretroviral regimens. However, it is important to bear in mind that cost and efficacy are not the only factors that influence the choice of antiretroviral therapy in HIV. Clinician preferences, the low incidence of other side effects (e.g., lipodystrophy), and other factors such as blood–brain barrier penetrance favor abacavir therapy. More important, HIV mutation and resistance to antiretrovirals mean that clinicians require the availability of all anti-HIV treatments, of which abacavir is one of a finite number [205]. Screening for *HLA-B*57:01* is now the most frequently used pharmacogenetic test in clinical practice.

20.4.3.2 Carbamazepine Hypersensitivity

Carbamazepine (CBZ) is an important drug that is used in the treatment of epilepsy, trigeminal neuralgia, and bipolar disorder [214–216]. Cutaneous ADRs have been reported with CBZ in up to 10% of patients [214]. These reactions can range from MPE to severe HSS or life-threatening SJS/TEN [217]. The annual incidence of SJS has been estimated to be 1–6 cases per million, and TEN has an incidence of approximately 1–2 cases per million. Of cases of TEN, 80–95% are believed to be drug-induced while 50–80% of cases of SJS are attributable to drugs [218]. The drugs most commonly associated with SJS/TEN are nevirapine, anticonvulsants (carbamazepine and lamotrigine), antibiotics (sulphonamides and aminopenicillins), allopurinol, and oxicam nonsteroidal anti-inflammatory agents [219]. Other causes of SJS/TEN include vaccination, mycoplasma pneumonia infection, dengue virus, and intravenous administration of contrast agents [220]. TEN is associated with significant mortality, up to 40%, and long-term morbidity, including blindness and scarring [217].

Researchers from Taiwan were the first to report a very strong association between *HLA-B*15:02* and CBZ-induced SJS among a Han Chinese population ($\text{OR}=2504$, $p=3.1\times10^{-27}$, 95% CI 126–49,522) [221]. This association was replicated in Han Chinese patients from China and Asian populations including Thai, Malay, and Indian [222–228]. However, it should be noted that European, Japanese, and Korean patients with CBZ-induced SJS/TEN did not demonstrate this association. Furthermore, *HLA-B*15:02* was not associated with other forms of CBZ-induced cutaneous ADR (HSS or MPE). Therefore, the association between *HLA-B*15:02* and CBZ-induced ADR is specific to both phenotype and ethnicity.

The incidence rate of SJS/TEN in some Southeast Asian countries, such as Taiwan, Malaysia, and Thailand, is 10-fold higher than the rates observed in Europe, the United States, or Japan [229]. This discrepancy may be explained by the differing background allele frequencies among different populations: the prevalence of *HLA-B*15:02* is highest among Asian populations (0.057–0.145 in Han Chinese, 0.085–0.275 in Thais, and 0.12–0.157 in Malays) compared with European (0.01–0.02), Japanese (0.002), and Korean (0.004) populations [229]. A systematic review demonstrated that carriage of the *HLA-B*1502* allele was associated with a 100-fold risk of developing SJS/TEN with CBZ [230]. The number needed to test in order to avoid an episode of CBZ-induced SJS/TEN was estimated to be 461. The clinical utility of preprescription studies was demonstrated by a prospective cohort study conducted in Taiwan [231], in which 4877 patients were prospectively genotyped for *HLA-B*15:02* and patients who were positive were prescribed alternative therapy to CBZ. The percentage of patients positive for *HLA-B*15:02* was 7.7. Based on the historic incidence of CBZ-induced SJS/TEN, 10 cases of SJS would have been expected, but in the Taiwanese study no patients developed either condition.

Two cost-effectiveness studies, in Thailand and Singapore, concluded that screening for *HLA-B*15:02* could be cost-effective in certain ethnicities, such as Singaporean Chinese and Malays, but would depend on population frequency of *HLA-B*15:02*, duration of treatment, PPV, and costs of alternative drugs and of the genotyping test itself [232,233]. On the basis of these data, the FDA and the European Medicines Agency now include warnings on the drug label advising clinicians of the need to genotype patients from certain areas of Asia prior to commencing therapy with CBZ [234].

In Japanese and Korean patients *HLA-B*15:11* has been associated with CBZ-induced SJS/TEN [235,236]. However, this association needs to replicated in larger numbers of patients and other populations in Europe before it can be considered as a screening test for CBZ-induced cutaneous ADRs.

Two GWAS, in Caucasian and Japanese patients, independently reported associations between *HLA-A*31:01* and all phenotypes of CBZ hypersensitivity, unlike *HLA-B*15:02*, which was phenotype specific for SJS/TEN [237,238]. This association was also demonstrated in Han Chinese and Korean patients [236,239]. Carriage of *HLA-A*31:01* was associated with a 9-fold increased risk of CBZ cutaneous ADR, and the number needed to test to avoid one case was between 47 and 67 depending on ethnicity [230].

20.4.3.3 Allopurinol Hypersensitivity

Allopurinol is a xanthine oxidase inhibitor indicated for the treatment of gout and hyperuricemia [240]. A case-control study in Han Chinese patients first reported an association between *HLA-B*58:01* and allopurinol-induced SJS/TEN and HSS [241]. In this study, all 51 patients who had developed allopurinol-induced SJS/TEN or HSS were positive for *HLA-B*58:01* compared with 20 out of 135 allopurinol-tolerant controls (15%) and 19 out of 93 (20%) in the general population ($OR = 580$, $p_c = 4.7 \times 10^{-24}$, 95% CI 34–9781). The association was replicated in patients from other Southeast Asian countries, including Thai, Japanese, and Korean [235,242–245]. In contrast to the association with CBZ, *HLA-B*58:01* was also identified as a potential biomarker for allopurinol-induced SJS/TEN and HSS in European populations [246]. A genome-wide association study (GWAS) in 14 Japanese patients with allopurinol-induced SJS/TEN identified the single nucleotide polymorphism (SNP) rs9263726 in *PSORS1C1* to be strongly associated with these conditions ($OR = 61.2$, $p = 3.64 \times 10^{-8}$, 95% CI 18.4–203.5). This SNP was in absolute linkage disequilibrium with *HLA-B*58:01* and may represent a simple and useful biomarker for screening prior to allopurinol therapy in Japanese patients. More recently, an association has been reported between *HLA-B*5801* and allopurinol-induced MPE in a Han Chinese population from China [242]. In this cohort, all 22 patients with allopurinol-induced MPE possessed *HLA-B*5801* compared with 7 out of 63 allopurinol-tolerant controls (11.1%) ($OR = 339$, $p = 9.2 \times 10^{-14}$, 95% CI 18.6–6186.4). However, the association between *HLA-B*58:01* and MPE needs to be replicated in other populations. The clinical utility of preprescription genotyping for *HLA-B*58:01* has not been determined and requires further research before it can be employed in routine clinical practice.

20.4.3.4 Maculopapular Exanthema Reactions

MPE is the most common cutaneous manifestation of ADR and accounts for 90–95% of skin reactions [247]. It presents as a diffuse cutaneous erythema with areas of skin elevation that usually appear on the trunk and spread to the extremities in a symmetrical pattern. Pruritus, low-grade fever, and eosinophilia are frequently present. The reaction usually presents in the first 7–14 days on first exposure but reappears more rapidly, 2–3 days, on re-exposure. MPE is usually self-limiting and clears 1–2 weeks following withdrawal of the causative agent [248]. In some cases, it can progress to more severe manifestations of DISI, but predicting which cases will progress is not possible at present. The drugs associated most frequently with MPE are penicillins, sulphonamides (especially co-trimoxazole), and NSAIDs [247]. Genetic associations to MPE have been reported; these are caused by antituberculous treatment and antiepileptic therapies.

Antituberculosis Medications

Treatment for TB is commonly associated with MPE reactions and has an estimated incidence of 0.1–5.7% among patients receiving first-line agents: isoniazid, rifampicin, ethambutol, and pyrazinamide [249]. In some cases, patients need to discontinue medication or change to other less effective regimens, leading to delay in TB treatment [250]. A recent study reported that polymorphisms in *CYP2C19* and *CYP2C9* were significantly associated with an increased risk of developing antiTB drug- (ATD-) induced MPE [251]. In this study, 62 patients with first-line ATD-MPE were compared against 159 patients without any adverse events to first-line ATD. The SNP −1565 C>T in *CYP2C9* showed a significant association with ATD-induced MPE, with fewer patients carrying the minor alleles (CT or TT) in cases compared with controls (4.9% versus 18.5%, $p_c = 0.022$, $OR = 0.23$, 95% CI 0.07–0.78). The SNP −636 G>A in *CYP2C19* (*CYP2C19*3*) was also significantly associated with susceptibility to ATD-induced MPE. Only 6.6% of patients with ATD-induced MPE carried the minor allele-containing genotypes (GA or AA) compared with 19.1% of ATD-tolerant controls ($p_c = 0.042$, $OR = 0.27$, 95% CI 0.09–0.82). One haplotype of *CYP2C9* and *CYP2C19* containing both significant SNPs (−1418 C>T-636 G>A-1565 C>T_−1188 C>T) was significantly associated with development of ATD-induced MPE ($p = 0.012$, $OR = 0.13$, 95% CI 0.03–0.57). No significant associations were reported between polymorphisms in *NAT2* and *CYP2E1* and ATD-induced MPE.

CYP2C9 and CYP2C19 are involved in the metabolism of both rifampicin and isoniazid [252]. Carriage of the *CYP2C9* polymorphism −1565 C>T appears to be protective against ATD-induced MPE. The functional significance of this polymorphism is currently not known, but has been hypothesized to affect either enzyme expression or enzyme activity, thereby affecting drug metabolite synthesis [251]. The polymorphism also demonstrates high linkage disequilibrium with the *CYP2C19*3* polymorphism, and it may be that the association between *CYP2C9* −1565C>T is actually related to altered CYP2C19 activity. *CYP2C19*3* is a poor metabolizer phenotype with a frequency of 0.06–0.10 among Asian populations [253]. Carriage of *CYP2C19*3* was protective for ATD-induced MPE, suggesting that modified metabolism and metabolite formation may be responsible for susceptibility to ATD-induced MPE [251].

20.4.3.5 Antiepileptics

Antiepileptic drugs (AEDs) are one of the most common culprits in triggering DISI. Carbamazepine (CBZ), lamotrigine (LTG), and oxcarbazepine (OXC) have all been associated with MPE [254,255]. When a patient develops a cutaneous ADR with AED therapy, early withdrawal of treatment is necessary because late withdrawal has been associated with negative outcome in patients who progress to more severe forms of DISI [256]. Several associations have been reported between AED-induced MPE and HLA [237,239,257–259].

A significant association between CBZ-induced MPE and *HLA-A*31:01* was originally reported in Han Chinese patients from Taiwan [239]. In this cohort, 18 patients were diagnosed with CBZ-induced MPE and 6 carried the *HLA-A*31:01* allele; this compared with only 6 in the CBZ-tolerant group ($p_c = 2.2 \times 10^{-3}$, OR = 17.5, 95% CI = 4.6–66.5). This association was replicated in European patients, where 22% with CBZ-induced MPE were positive for the *HLA-A*31:01* allele compared with only 4% who were CBZ tolerant ($p = 8.0 \times 10^{-7}$, OR = 8.33, 95% CI 3.59–19.36) [237]. More recently, a larger study of Han Chinese patients identified four new risk alleles for the development of CBZ-induced MPE [258]. Two alleles, *HLA-A*02:01* and *HLA-DRB1*14:05*, were found at significantly increased frequency among CBZ-induced MPE patients compared with tolerant controls (p = 0.033 and 0.003, respectively). *HLA-B*58:01* was present in 4% of CBZ-MPE patients compared with 13% of CBZ-tolerant controls, and the frequency of *HLA-DRB1*03:01* in CBZ-MPE patients was 4% compared with 13% in tolerant controls. These studies suggest that the *HLA-A*31:01*, *HLA-A*02:01*, and *HLA-DRB1*14:05* alleles increase the risk of CBZ-induced MPE, whereas *HLA-B*58:01* and *HLA-DRB1*03:01* protect against it.

LTG is an anticonvulsant with an aromatic ring structure similar to that of CBZ. It is associated with cutaneous ADRs with a reported frequency of approximately 4.8% [260]. Three alleles have been associated with LTG-induced MPE: *HLA-A*30:01*, *HLA-B*13:02*, and *HLA-A*33:03* [258]. The frequency of *HLA-A*30:01* and *HLA-B*13:02* was significantly increased in patients with LTG-induced MPE compared with LTG-tolerant controls. *HLA-A*33:03* appeared to have a protective effect, with 3% of LTG-MPE patients carrying the allele compared with 11.4% of LTG-tolerant controls (p = 0.048). However, it is important to note that two other studies failed to detect any significant associations between HLA alleles and LTG-induced cADR [261,262].

OXC is an analog of CBZ with antiseizure efficacy equivalent to that of CBZ. It is considered to be safer than CBZ because of its metabolism via alternative metabolic pathways, and has therefore been recommended as an alternative to CBZ [255,263]. However, recent studies have reported the incidence of OXC-induced cutaneous ADR to be similar to that resulting from CBZ, at 8%–9% [264,265]. *HLA-B*15:02* was reported to be significantly associated with OXC-induced MPE in a population of Han Chinese patients [257]. In this study, 44.4% of patients with OXC-induced MPE possessed the *HLA-B*15:02* allele compared with 11.1% in the OXC-tolerant group and 8.3% among population controls. However, only the association between OXC-induced MPE patients and population controls reached significance (OR = 8.8, p = 0.011, 95% CI 1.853–41.790). A second study of Han Chinese patients failed to replicate this association, with only 3.6% of patients with OXC-induced MPE positive for *HLA-B*15:02* [259]. This study did report that *HLA-B*13:02*, with a frequency of 14.3% among OXC-MPE patients compared with 2.1% in the general population, is a significant risk allele for OXC-induced MPE (OR = 7.83, p = 0.001, 95% CI 2.32–26.41). It must be noted that both of these studies included small numbers of patients and require further validation in much larger cohorts.

20.4.4 Drug-Induced Liver Injury

Drug-induced liver injury (DILI) is a rare, but potentially fatal, adverse hepatic reaction to medication. Because it is usually unexpected on the basis of the pharmacological action of the drug administered, it is distinct from DILI secondary to drug overdose, such as acetaminophen, where the risk and severity of injury generally increases with the dose taken [266]. DILI has an estimated incidence of 1–10 per 100,000 in patients exposed and accounts for up to 15% of acute liver failure cases in Europe and the United States. It is the single most common adverse effect leading to drug withdrawal or FDA refusals to approve [267]. Drugs that cause DILI are chemically diverse and belong to a multitude of therapeutic classes. In the majority of treated patients, these drugs are safe over a wide range of dosages, but a small subset of patients experience severe ADRs (e.g., DILI). Because of this unpredictability and low incidence of

TABLE 20.11 Drug-Induced Liver Injury and Reported Genetic Associations

Drug	Class of Drug	Genetic Association	Ethnicity
Amoxicillin-Clavulanate	Antibiotic	*DRB1*15:01*	Caucasians
		*A*02:01*	Spanish
		*B*18:01*	
Flucloxacillin	Antibiotic	*B*57:01*	Caucasian

events, a drug's hepatotoxic potential may be realized only after it has obtained market approval and large numbers of patients have been exposed [268–270].

Diagnosis of DILI is difficult because of variability in presentation, heterogeneity of hepatotoxic medications, and lack of understanding of the pathophysiology of liver injury. A case definition and diagnostic algorithm for DILI has been published that will improve diagnostic accuracy and identification of culprit medications [266]. The mechanism of drug-induced hepatotoxicity is a complicated multistep process that involves direct injury to the hepatocytes and activation of inflammatory pathways. It is thought that initial events in DILI are drug specific, and that the drug and/or its metabolites directly cause cell stress, trigger immune response, and/or impair mitochondrial function. Subsequent "downstream" steps are less specific, and common to all drugs, representing a balance between protective and toxic pathways. In susceptible individuals, apoptotic or necrotic cell death is initiated when "mitochondrial permeability transition" is activated as toxic pathways overcome protective mechanisms [271].

Risk factors for DILI susceptibility include genetic variation in drug metabolism pathways and immune response [272]. As with DISI, several associations have been reported between HLA and DILI (Table 20.11). This is a little surprising because the clinical features of DILI with some drugs (e.g., lumiracoxib, ximelagatran) do not suggest an immune component [273,274]. Despite the strong associations reported by some studies, none of these tests have been translated into clinical practice.

20.4.4.1 Amoxicillin-Clavulanate

Amoxicillin-clavulanate (AC) is one of the most commonly prescribed antibacterials worldwide. It is an important cause of DILI, accounting for approximately 10–13% of DILI-related hospitalizations [275,276]. The clinical presentation of AC-induced DILI is varied, with most patients recovering after cessation of AC but with a minority developing acute liver failure leading to mortality or requiring transplantation [277,278]. An association between HLA and AC-DILI was first reported in a European population where the frequency of the haplotype *HLA-DRB1*15:01-DRB5*01:01-DQB1*06:02* was significantly higher in the group with AC-DILI compared with population controls (57.1% versus 11.7%, $p_c < 0.0002$) [279]. This association was replicated in two UK populations [280,281]. In the first cohort, 14 of 20 AC-DILI patients (70.0%) were positive for *HLA-DRB1*1501* compared with 27 of 134 controls (20.1%) ($OR = 9.3$, $p < 2.5 \times 10^{-6}$). All patients positive for *HLA-DRB1*1501* also possessed the *HLA-DRB1*15:01-DRB5*01:01-DQB1*06:02* haplotype, as reported in the first AC-DILI study [280]. The third study confirmed the association between *HLA-DRB1*15:01* and AC-DILI (OR = 2.6, p = 0.002, 95% CI 1.44–4.68), but also identified a protective genotype, *HLA-DRB1*07* (OR = 0.266, $p_c = 0.0266$, 95% CI 0.11–0.65) [281].

It should be noted that *HLA-DRB1*15:01* was not significant in a Spanish cohort of patients with AC-DILI [282]. A GWAS study involving 201 patients of White European or U.S. origin with AC-DILI replicated the association between *HLA-DRB1*15:01* and AC-DILI (OR = 4.2, $p = 4.6 \times 10^{-6}$, 95% CI 2.7–6.6). Two novel risk HLA alleles were also identified: *HLA-A*02:01* (OR = 2.2, $p = 2.0 \times 10^{-6}$, 95% CI 1.6–3.2) in all patients, and *HLA-B*18:01* (OR = 4.0, p = 0.004, 95% CI 1.5–11) in Spanish patients only [283]. Carriers of both *HLA-DRB1*15:01* and *HLA-A*02:01* have approximately a 10-fold increased risk of AC-DILI. Assuming a 0.014% incidence of AC-DILI, the PPV and NPV for testing both alleles is 0.1% and 99.9%, respectively. This low PPV means that prospective genotyping is unlikely to be effective at identifying those at risk of DILI but may have clinical utility in strengthening AC-DILI diagnoses.

20.4.4.2 Flucloxacillin

Flucloxacillin is an antimicrobial agent used widely in Europe for treatment of methicillin-sensitive staphylococcal infections. Flucloxacillin use has been associated with a characteristic cholestatic hepatitis with an estimated incidence of 8.5 per 100,000 users [284]. A GWAS in 51 patients reported a strong association between *HLA-B*57:01* and flucloxacillin DILI (OR = 80.6, $p = 9.0 \times 10^{-19}$, 95% CI 22.8–284.9) [285]. A replication cohort of 23 further cases of flucloxacillin DILI confirmed the association (OR = 100.0, $p = 6.62 \times 10^{-13}$, 95% CI 20.6–485.8). Therefore, patients positive for *HLA-B*57:01* have an estimated 100-fold greater risk for DILI with flucloxacillin therapy. Despite this strong association, only 1 in 500–1000 patients with the *HLA-B*57:01* genotype who are undergoing flucloxacillin therapy will develop DILI. The sensitivity and specificity for pretreatment screening for *HLA-B*57:01* was high—87% and 94% respectively—but because of low incidence of flucloxacillin DILI, the PPV for the test was only 0.12%. To avoid one case of flucloxacillin-induced DILI, more than 13,500 patients would need to be screened. Furthermore, because of the low PPV, many patients who would not have developed DILI with flucloxacillin would also be denied this effective treatment [286]. At present, isolated *HLA-B*57:01* genotype screening prior to therapy is neither clinically effective nor cost-effective for routine clinical practice, but it may be of use diagnostically in patients who have developed liver manifestations where there are competing etiologies. It is interesting that *HLA-B*57:01* is also associated with abacavir hypersensitivity syndrome despite its clinical presentation being markedly different—DISI versus DILI (see above).

20.4.4.3 Ximelagatran

Ximelagatran was the first commercially available oral direct thrombin inhibitor. It was demonstrated to be equally effective as the conventional anticoagulant (warfarin) without the requirement of regular monitoring. Routine clinical and preclinical toxicological studies did not identify ximelagatran as a cause of DILI, but the drug was withdrawn from clinical development in 2007 because long-term analyses reported an association with hepatotoxicity in some patients [287]. Following drug withdrawal, a GWAS identified an association in both the exploratory and replication cohorts between ximelagatran-induced DILI and HLA alleles *DRB1*07:01* (OR = 4.4, $p_{min} = 9.1 \times 10^{-6}$, 95% CI 2.2–8.9) and *DQA1*02:01* (OR = 4.4, $p_{min} = 1.3 \times 10^{-5}$, 95% CI 2.2–8.8) [273].

It is interesting that the frequency of *HLA-DRB1*07:01* has a carrier frequency of >10% in European populations compared with 0.3% in Japanese populations [288]. The allele frequency distribution is consistent with the observation that ximelagatran DILI has a higher incidence in European populations compared with Asian populations and represents a situation similar to that of CBZ SJS/TEN and *HLA-B*15:02* [289]. The association between ximelagatran DILI and HLA alleles is surprising because the clinical phenotype of injury does not suggest an immune component. Results from lymphocyte transformation and major histocompatibility binding (MHC) tests suggest that ximelagatran is immunogenic and able to inhibit the binding of peptides to *HLA-DRB1*0701* [273]. A pharmacogenetic screening test for *HLA-DRB1*07:01* before ximelagtran therapy would have 47–50% sensitivity, 83–97% specificity, 19–59% PPV, and 95–96% NPV. Assuming an incidence of elevated alanine aminotransferases (>3 times the upper limit of normal) in 8% of patients prescribed long-term treatment with ximelagatran, between 20–24 patients would need to be screened to prevent one case of ximelagatran DILI [286,289]. Such numbers compare favorably to other screening tests, such as mammography in the identification of breast cancer [290]. These results are only based on one study, which cannot be replicated because the drug has been withdrawn, and so they need to be interpreted with caution.

20.4.4.4 Lumiracoxib

Lumiracoxib, a cyclo-oxygenase-2 selective inhibitor for treatment of pain and osteoarthritis, was withdrawn from the market or not approved following cases of severe hepatotoxicity in 2007. A GWAS compared lumiracoxib-treated patients with DILI against lumiraxocib-tolerant patients and reported a significant association with the MHC class II haplotype: *HLA-DRB1*15:01-HLA-DQB1*06:02-HLA-DRB5*01:01-HLA-DQA1*01:02* (OR = 5.0, $p = 6.8 \times 10^{-25}$, 95%

CI 3.6–7.0) [274]. Interestingly, the allele *HLA-DRB1*15:01* has also been implicated in AC-induced DILI, which suggests a possible overlap in pathogenesis of DILI despite differences in drug structure and DILI's clinical phenotype.

20.4.4.5 Other Drugs

Candidate gene studies have identified HLA associations with nevirapine-, lapatinib-, and ticlopidine-induced DILI [291–295]. Nevirapine is a widely prescribed non-nucleoside reverse transcriptase inhibitor for the treatment of HIV infection; it is associated with significantly increased frequency of hepatotoxicity compared with other antiretroviral therapies [296]. *HLA-DRB1*01:01* was significantly associated with nevirapine-induced DILI in a White Australian cohort with high CD4 T-cell counts ($OR = 3.02$, $p_c = 0.0074$, 95% CI 1.66–5.49). The association did not reach significance in Asian or black populations because of a low background frequency of the *HLA-DRB1*01:01* genotype and smaller sample sizes [292].

Lapatinib, a tyrosine kinase inhibitor, is used in the treatment of patients with advanced and metastatic breast cancer; it is associated with hepatobiliary disorder in up to 8% of patients [297]. *HLA-DQA1*02:01* was more common among patients with elevated alanine transaminase on lapatinib therapy compared with lapatinib-treated controls ($OR = 2.6$, $p = 0.03$, 95% CI 1.1–5.7). The association was confirmed in a replication cohort ($OR = 9.0$, $p = 0.0008$, 95% CI 3.2–27.4). As a predictor of lapatinib hepatotoxicity, *HLA-DQA1*02:01* had NPV and PPV of 0.97 and 0.17, respectively [293].

Ticlopidine is an antiplatelet agent that is associated with DILI; it is primarily of a cholestatic phenotype, with increased frequency in Japanese patients relative to Caucasian patients [298]. An initial case study in 22 Japanese patients with ticlopidine-induced DILI reported a significant association with *HLA-A*33:03* ($OR = 13.0$, $p_c = 1.24 \times 10^{-5}$, 95% CI 4.4–38.6) [294]. A second study reported that Japanese patients were most susceptible to ticlopidine DILI if they were positive for both *HLA-A*33:03* and *CYP2B6*1H* or *1J* ($OR = 38.8$, $p < 0.001$, 95% CI 8.8–196.0) compared with patients possessing only *HLA-A*33:03* ($OR = 15.5$, $p = < 0.001$, 95% CI 4.9–59.3) [295]. CYP2B6 is one of the key enzymes responsible for the formation of the toxic S-oxide metabolite of ticlopidine, which is hypothesized to be responsible for liver injury [299]. This study is the first to report a significant association between susceptibility to ADRs and a combination of polymorphisms in drug metabolizing enzymes and HLA.

20.5 CONCLUSION

Significant developments and breakthroughs during the past decade have increased our understanding and knowledge of genetic susceptibility to ADRs. However, apart from isolated examples such as TPMT genotyping and *HLA-B*57:01* screening in abacavir therapy, no pharmacogenetic test for ADR susceptibility has been translated into clinical practice. Clinical implementation of pharmacogenetic biomarker tests is difficult but can be split into four phases: T1 (discovery); T2 (clinical validity and utility); T3 (implementation); and T4 (effect on public health) [300]. Much of the research discussed in this chapter remains trapped in T1. This is for a multitude of reasons, including poor study design, inadequate sample sizes, lack of replication, and heterogeneity among patient populations.

Despite the many genetic associations being reported, replication has proven difficult because of the large numbers of patients and controls required. Many studies are retrospective, where patient phenotypes are recorded inaccurately and other crucial factors (e.g., drug dosage/timing, concomitant medications) are missing. Reports have estimated that only 30–50% of reported cases of DILI are correctly diagnosed or classified [301,302]. In future studies, phenotype standardization and development of diagnostic algorithms will help to improve diagnosis [193,266]. The arrival of international networks and consortia—the Drug-Induced Liver Injury Network in the U.S. (DILIN; https://dilin.dcri.duke.edu), the European collaboration to establish a case-control DNA collection for studying the genetic basis of adverse drug reactions, known as EUDRAGENE (www.eudragene.org), and the International Serious Adverse Events Consortium (SAEC; www.saeconsortium.org), among others—will enable larger samples to be collected across multiple populations and will ensure more accurate data recording.

Accurate phenotype recording is crucial because different phenotypes are likely to have diverse pathophysiological mechanisms, and combining diverse phenotypes reduces the power of a study to detect significant associations. This has been highlighted by the phenotype specificity of *HLA-B*15:02*, which is significantly associated with CBZ-induced SJS/TEN but not with HSS or MPE [221]. As well as being phenotype specific, *HLA-B*15:02* and CBZ-SJS/TEN is ethnicity specific, with the association relevant in Asian populations but not in Europeans, Japanese, or Koreans [230]. Similarly, the association between AC-induced DILI and *HLA-DRB1*15:*01 has been reported in several European populations but not in Spanish patients [275]. Susceptibility to ticlopidine hepatotoxicity is associated with an increased frequency of *HLA-A*33:03* in Japanese, but not Caucasian, populations [295]. Ethnic specificity is believed to be due to different background frequencies of the risk HLA alleles. The frequency of *HLA-A*33:03* in Japanese patients (0.1280) is significantly higher than in English (0.003), Portuguese (0.011), or Italian (0.000) populations (www.allelefrequencies.net).

In some cases, combinations of genetic polymorphisms may increase susceptibility to ADRs, as highlighted by the increased risk of ticlopidine-DILI in Japanese patients positive for both *HLA-A*33:03* and *CYP2B6*1H* or **1J*, compared with carriage of the HLA allele alone [295]. It is likely that most ADRs are polygenic and that each gene has a small overall effect. By recruiting large numbers of patients and screening for multiple genetic polymorphisms (metabolizing enzymes, drug transporters, drug receptors, immune system variation), we may be able to improve accuracy of ADR prediction in the future. A pharmacogenetic score combining three SNPs accurately predicted and stratified those patients with stable coronary artery disease into those most likely to benefit or, conversely, suffer harm from perindopril therapy, highlighting the utility of such an approach [303].

At present, next-generation sequencing (NGS) has not been utilized to investigate the role of genetics in ADRs. NGS allows analysis of rare variants, which cannot be detected by GWAS, that have been postulated to have larger effect sizes and more likely to be functionally relevant compared with common variants [304]. Epigenetics is the study of mitotically heritable changes in gene expression that are not attributable to nucleic acid sequence alterations. A recent review article discussed the role of epigenetics in ADRs, concluding that, with the advent of NGS, we are likely to significantly increase our understanding of the role of the epigenome in drug response [305,306].

Many proposed pharmacogenetic tests for ADR susceptibility have high NPVs and low PPVs because of the low incidence of some ADRs [211,230,286]. This means that a significant number of patients who test positive for the suspected allele will never develop hypersensitivity, or that very large numbers of patients need to be tested in order to avoid one ADR diagnosis. This has major clinical implications because patients may be denied optimal treatment or require more costly alternative therapies, or because the pharmacogenetic test itself is not cost-effective [286]. Prospective randomized trials to assess the utility of preprescription genetic testing will be difficult to undertake in cases where the incidence of ADR is very low. This raises the question as to the type of evidence needed to demonstrate a test's clinical utility that will be acceptable to prescribing clinicians. However, for other phenotypes that require dose adjustment or where the phenotype of interest is common, it may be possible to undertake randomized trials, as is currently being done with warfarin.

Any genetic screening test for ADRs must also demonstrate cost-effectiveness in clinical practice. ADRs that have severe clinical or economic consequences and have a clear association between genotype and phenotype, and for which there is a rapid and inexpensive genetic test with a high frequency of associated variant gene—these are more likely to be cost-effective [307].

Vanderbilt University has been developing a very large biobank linking phenotype data from clinical records to genotype data gathered from routine patient blood samples (which otherwise would have been discarded) [308]. The biobank enables rapid collection of samples, 700–900 per week, diverse phenotype recruitment, and active real-time monitoring of the effects of changes in drug choice or dosage and the chosen drug's effect on clinical outcome. In Canada, a comprehensive nationwide surveillance network—the Canadian Pharmacogenomics Network for Drug Safety (CPNDS)—was established with the goal of identifying patients with ADRs and ensuring collection of relevant biological samples and accurate clinical histories [309]. It successfully identified novel biomarkers for cisplatin-induced deafness and codeine-induced infant mortality.

Moving forward, active ADR surveillance is necessary to increase identification and recruitment of patients suffering from ADRs. In order to translate pharmacogenetic associations into successful clinical practice, collaboration will be required between scientists, clinicians, government agencies, and pharmaceutical and technology companies.

ABBREVIATIONS AND ACRONYMS

6-MP	6-mercaptopurine
AC	amoxicillin-clavulanate
ADR	adverse drug reaction
AGEP	acute generalized exanthematous pustulosis
AHS	abacavir hypersensitivity syndrome
ALL	acute lymphoblastic leukemia
AZA	azathioprine
CBZ	carbamazepine
CHCT	caffeine halothane contracture test
CK	creatine kinase
DILI	drug-induced liver injury
DISI	drug-induced skin injury
DZ	dizygotic
EM	extensive metabolizer
EMHG	European Malignant Hyperthermia Group
eQTL	expression quantitative loci
FDA	U.S. Food and Drug Administration
GWAS	genome-wide association study
HIV	human immunodeficiency virus
HLA	human leukocyte antigen
HSS	hypersensitivity syndrome
IM	intermediate metabolizer
INR	international normalized ratio
IVCT	*in vitro* contracture test
IWPC	International Warfarin Pharmacogenetics Consortium
LTG	lamotrigine
MH	malignant hyperthermia
MHC	major histocompatibility complex
MPE	maculopapular exanthema
MZ	monozygotic
NAMHG	North American Malignant Hyperthermia Group
NAT	N-acetyltransferase
NGS	next-generation sequencing
NHS	National Health Service
OXC	oxcarbazepine

PM	poor metabolizer
RCT	randomized control trial
SJS	Stevens-Johnson syndrome
SMX	sulfamethoxazole
TB	tuberculosis
TEN	toxic epidermal necrolysis
TPMT	thiopurine methyl S-transferase
UGT	uridine diphosphate glucuronyltransferase
URM	ultrarapid metabolizer
VKOR	vitamin K epoxide reductase
VKORC	vitamin k epoxide reductase subunit 1
